LIBRARY

Foreword

This volume presents an integration of the results of the researches sponsored by the Herman Frasch Foundation for Research in Agricultural Chemistry at the Missouri Agricultural Experiment Station. The major purpose of these investigations was to make a comparative study of the energetic efficiencies of agricultural processes, such as those concerned in the production of meat, milk, eggs, and muscular work, along with the factors influencing these efficiencies. The field is a very broad one and the discussions in this volume range over a wide territory. They include such important considerations as the energy cost of maintaining animals, of transforming feed into body tissue, milk, eggs, and other desired products, the relation of the speed with which the transformations occur to the efficiency of the process, the influence of the size of the producing animal on the efficiency and profit of the productive enterprise, and the influence of the rate of the process on the rate of aging. Many of the factors influencing efficiency, such as enzymes, minerals, vitamins, and hormones, are analyzed, largely with the aid of available literature.

The broad research project, the results of which are reported herein, was an institutional enterprise involving the cooperation of four departments in the Missouri Agricultural Experiment Station,—Dairy Husbandry, Animal Husbandry, Poultry Husbandry, and Agricultural Chemistry. The chairmen of these respective departments—A. C. Ragsdale, E. A. Trowbridge, H. L. Kempster, and A. G. Hogan—constituted the research committee, with the author of this volume serving as leader. The research plan was organized under the direction of Dean F. B. Mumford, who was Director of the Missouri Agricultural Experiment Station during most of the period of this investigation.

Many technical aspects of this research have been published as research bulletins of the Missouri Station and as technical articles in scientific journals. This volume brings together in integrated form the essential material incorporated in these many publications, along with much additional material brought together by the author.

The Frasch Foundation and its technical adviser, The American Chemical Society, working through its trustee, The United States Trust Company of New York, was represented on this research project during part of this period by Dr. R. W. Thatcher, distinguished agricultural chemist and president of the Massachusetts State College of Agriculture. Most of the long-range bioenergetic plans were formulated with Dr. Thatcher's advice and encouragement. Following Dr. Thatcher's death, this position was ably filled by two other

representatives of Land Grant College staffs—first, by Dr. F. J. Sievers, Director of the Massachusetts Agricultural Experiment Station, and later by Dr. H. R. Kraybill, Head of the Department of Agricultural Chemistry of Purdue University. Dr. Kraybill has organized the plan through which the publication of the book was made possible.

This volume provides an excellent example of the results of a cooperative effort between an important private Foundation interested in the field of agriculture and an Agricultural Experiment Station associated with one of the Land Grant Colleges. The success of this cooperative endeavor in the development of a large volume of valuable research data and in its publication for general use, offers encouragement for similar plans of cooperation in the future.

The author desires to express his grateful appreciation to the Guggenheim Foundation for a European traveling Fellowship in connection with the preparation of this volume.

M. F. MILLER, *Director,*
Missouri Agricultural Experiment Station

CHAPTER 1

INTRODUCTION: FACTORS IN THE EFFICIENCY COMPLEX

<i>Section</i>	<i>Page</i>
1.1—Efficiency and profit, immediate and long range.....	1
1.2—Growth, form, and function.....	2
1.3—Organizational energy or the energy expended for the “work” of growth and morphogenesis.....	2
1.4—Basal metabolism, maintenance cost, and efficiency.....	4
1.5—Nutritional categories.....	5
1.6—Organismic and atomistic viewpoints.....	6
1.7—Appendix.....	10

CHAPTER 2

ENERGETICS, ENERGY UNITS, AND DIETARY-ENERGY CATEGORIES

2.1—Energetics.....	12
2.2—Energy units and energetic equivalents.....	23
2.3—Feed and nutrient energy categories.....	24
2.4—Summary and appendix.....	33

CHAPTER 3

ENERGETIC EFFICIENCIES OF GROWTH AND WORK PROCESSES

3.1—Energetic efficiency of muscular work and the maintenance complication.....	37
3.2—Energetic efficiency of growth and the maintenance complication.....	40
3.3—Energetic efficiency of milk and egg production.....	53
3.4—Relation between the net energy category of feed and the efficiency of productive processes.....	54
3.5—Summary.....	57

CHAPTER 4

SPECIFIC DYNAMIC ACTION AND EFFICIENCY OF PRODUCTIVE PROCESSES

4.1—Specific dynamic action, basal metabolism, and endogenous nitrogen excretion.....	59
---	----

4.2—Plane of nutrition and SDA.....	67
4.3—Nutrient unbalance and SDA.....	70
4.4—Agricultural implications.....	72
4.5—Summary.....	74

CHAPTER 5

PLANE OF NUTRITION, THE PRINCIPLE OF DIMINISHING INCREMENTS, AND EFFICIENCY

5.1—The principle of diminishing increments.....	76
5.2—The principle of diminishing increments and the net energy values of cattle and rabbit feeds.....	79
5.3—The principle of diminishing increments and food consumption during growth.....	86
5.4—The principle of diminishing increments and milk production..	91
5.5—The principle of diminishing increments and egg production efficiency.....	95
5.6—The principle of diminishing increments and muscular-work efficiency.....	96
5.7—Summary and appendix.....	97

CHAPTER 6

METABOLIC CATALYSTS IN THE EFFICIENCY COMPLEX: ENZYMES, MINERALS AND VITAMINS IN BIOLOGIC OXIDATIONS

6.1—Introduction.....	100
6.2—Aerobic and anaerobic oxidations with special reference to intense muscular work.....	102
6.3—Oxidation-reduction potentials and biologic oxidation.....	104
6.4—Interrelations between minerals, vitamins, enzymes, and hormones in biologic oxidations: an illustration of unity in diversity	109
6.5—Note on biologic synthesis with special reference to CO ₂ assimilation in heterotrophs.....	128
6.6—Summary and appendix.....	131
I. B vitamins or bios.....	132
II. Ascorbic acid.....	134
III. Fat-soluble vitamins.....	135
IV. Mineral groups in oxidoreductions.....	136
V. General definitions.....	137

CHAPTER 7

METABOLIC CATALYSTS IN THE EFFICIENCY COMPLEX: HORMONES

7.1—Orientation.....	140
7.2—Hormones in reproduction and lactation.....	154

7.3—Energy-metabolism hormones, thyroid and adrenal-medulla . . .	168
7.4—Adrenal cortex	184
7.5—Calcium-phosphorus-metabolism hormones, the parathyroids . .	188
7.6—Carbohydrate-fat metabolism hormones	191
7.7—Anterior-pituitary and growth hormones	194
7.8—Notes on miscellaneous hormones	202
7.9—Summary	205

CHAPTER 8

METABOLIC CATALYSTS IN THE EFFICIENCY COMPLEX: SEASONAL RHYTHMS

8.1—Introduction	206
8.2—Historic notes	208
8.3—Mechanism of seasonal sex periodicity	209
8.4—Seasonal food supply rhythms in relation to seasonal sex activity.	211
8.5—Seasonal periodicity in relation to efficiency with special refer- ence to egg and milk production	213
8.6—Seasonal growth and metabolic rhythms	222
8.7—Summary	230

CHAPTER 9

METABOLIC CATALYSTS IN THE EFFICIENCY COMPLEX: DIURNAL RHYTHMS

9.1—Introduction	232
9.2—The literature	233
9.3—Diurnal metabolic rhythm in the rat, its control and effect on the apparent SDA	238
9.4—Summary	241

CHAPTER 10

HOMEOSTASIS AND ORGANISMIC THEORY

10.1—Introduction	243
10.2—Body-weight regulation	246
10.3—Body-water regulation	248
10.4—Carbohydrate-level regulation	248
10.5—Calcium-level regulation	249
10.6—Fat-level regulation	250
10.7—Oxygen and acid level regulation	250
10.8—Neuro-endocrine homeostasis	252
10.9—Social homeostasis	254
10.10—Notes on organismic or field theory and on research methods..	257
10.11—Summary	262

CHAPTER 11

HOMEOTHERMY, TEMPERATURE IN LIFE PROCESSES, AND PRODUCTIVE EFFICIENCY

11.1—Introduction	264
11.2—Relative productivities and efficiencies of homeotherms and poikilotherms	266
11.3—Temperature coefficients and the van't Hoff-Arrhenius equation in life processes	267
11.4—Age changes in homeothermy	271
11.5—Homeothermic mechanisms	274
11.6—Applications	290
11.7—Summary	304

CHAPTER 12

METHODS IN ANIMAL CALORIMETRY

12.1—Principles	307
12.2—Methods of indirect calorimetry	313
12.3—Food calorimetry	344
12.4—Historic comments	344
12.5—Summary and general comments	347

CHAPTER 13

BASAL ENERGY AND PROTEIN METABOLISM IN RELATION TO BODY WEIGHT IN MATURE ANIMALS OF DIFFERENT SPECIES

13.1—Definitions	352
13.2—Basal metabolism and the "surface law"	354
13.3—Metabolically-effective body size vs. surface area	360
13.4—Properties of equations relating surface area or metabolism to body size	365
13.5—Relation of basal energy metabolism to body weight in mature animals of different species	368
13.6—Relation of endogenous nitrogen, creatinine, and neutral sulfur excretion to body weight in mature animals of different species ...	374
13.7—Summary	383
13.8—Appendix	398

CHAPTER 14

METABOLISM AND PULMONARY VENTILATION IN RELATION TO BODY WEIGHT DURING GROWTH

14.1—Definitions	404
14.2—Metabolism in relation to body weight in the white rat, with notes on cerebral metabolism	406

14.3—Resting metabolism and pulmonary ventilation in dairy cattle . . .	409
14.4—Resting metabolism in goats	419
14.5—Resting metabolism and pulmonary ventilation in horses	420
14.6—Metabolism in man	425
14.7—Prenatal heat production in relation to birth weight	428
14.8—Estimating the heat increment of gestation and total prenatal heat production	440
14.9—Endogenous nitrogen excretion during growth	442
14.10—Metabolism per unit weight as function of weight and of age dur- ing rapid growth	447
14.11—Summary and conclusions	448

CHAPTER 15

MAINTENANCE NEEDS IN RELATION TO BASAL METABOLISM, BODY SIZE, AND PRODUCTIVE EFFICIENCY	470

Chapter 1

Introduction: Factors in the Efficiency Complex

The situation is complicated and its difficulties are enhanced by the impossibility of saying everything at once. *J. H. Woodger*

Ascertainable truth is piece-meal, partial, uncertain, and difficult.
B. Russell

The efficiency complex involves innumerable genetic and environmental, as well as physiologic and economic factors. This book represents an attempt to integrate some physiologic and economic factors influencing efficiency with special reference to investigations with which the writer has been associated. Special attention is called to the operation of the principles of diminishing returns, limiting factors¹, and organismic interrelations and compensations in the efficiency complex. Much of the subject matter under consideration is, frankly, not applicable to the operation of an agricultural enterprise. But such apparently impracticable investigations are extremely important, partly because they "have dignified the calling of agriculture and have given the farmer an intellectual background and basis for his thinking that cannot be easily measured"².

1.1: Efficiency and profit, immediate and long-range. The animal husbandman, by employing special techniques, finds it possible to accelerate the speed of growth, milk production, egg production, and muscular work, of his animals. Whether this increased productivity results in greater *immediate* energetic efficiency, of course, depends on the relative acceleration of the productive processes on the one hand and maintenance cost on the other. But supposing that an increase in immediate energetic efficiency occurs, how will this affect the future health, fertility, and longevity (factors in *long-range* efficiency) of the animal? How do successive production increments compare with successive immediate and long-range cost increments? Obviously, the efficiency complex must be viewed from four standpoints: that of the animal and that of the animal husbandman, that of immediate efficiency and that of long-range efficiency.

¹ Cf. Blackman, F. F., *Ann. Bot.*, **19**, 281 (1905); Liebig, J., "Die Chemie in innerer Anwendung auf Agrikultur", 1876.

² Mumford, F. B., "Fifty years of Agricultural Experiment Station Work". Address, Fiftieth Anniversary Exercises, University of Missouri, Agricultural Experiment Station, Columbia, June 21, 1938.

Energetic efficiency is the ratio of the desired form of output energy to the given form of input energy. In animals, the desired form of output energy is milk, meat, eggs, muscular work, wool, and so on; the input is a given category of feed energy, such as gross feed energy, digestible feed energy, metabolizable feed energy, net feed energy. *Gross efficiency** is the percentage of the energy in the given feed category, *inclusive of maintenance*, recovered in the desired product; *net efficiency*† is the percentage of the energy in the given feed category, *exclusive of maintenance*, recovered in the desired product.

But the problem does not end with *energetic efficiency*. *Monetary profit* offers a further and very substantial complication. Two 800-lb cows producing milk at the same energetic efficiency as one 1600-lb cow are not as profitable commercially. This is because the labor cost of milking, feeding, cleaning, housing, bookkeeping, etc., is nearly twice as great for two 800-lb cows as for one equally efficient 1600-lb cow, and the profit will be correspondingly less for the two small than for the one large cow. Energetic efficiency of milk production is a biologic index of "dairy merit", probably independent of body weight as such: rats, goats, and cows probably produce milk equally efficiently³ but not equally profitably (see Chs. 3 and 22). Profit is dependent not only on energetic efficiency—a biologic characteristic—but also on many other factors, including labor and other overhead costs per unit of milk production, which are in turn dependent on size of animal and other factors. Similar problems are involved in producing meat, eggs, wool, muscular work, and so on.

1.2: Growth, form, and function. Growth is the basis of and closely related to many productive agricultural processes. Egg, milk, fat, and wool production are special types of, or closely related to, growth. The function of an animal is, furthermore, related to its *form*, the development of which is a growth phenomenon. Growth, form, and function (*e.g.*, the production of meat, milk, eggs) are closely interrelated, and special emphasis has been given to various aspects of growth phenomena (Chs. 16 to 20).

1.3: Organizational energy or the energy expended for the "work" of growth and morphogenesis. One expense of the overall or gross productive cost is the transformation of the original feed into the final productive *precursors*, circulating in the blood stream, or in temporary storage in the body. But there must be another expense, that of transforming the relatively simple, amorphous precursors, or building stones, into the complexly organized and

$$* \text{ Gross efficiency} = \frac{\text{output energy (of milk, eggs, meat, work, etc.)}}{\text{input energy (of gross energy, TDN, etc.)}} \quad (1.1)$$

The term "gross" is preferred to "total" efficiency in order to avoid the implication that we are dealing with "total" energy changes.

$$\dagger \text{ Net efficiency} = \frac{\text{output energy}}{\text{input energy less maintenance energy}} \quad (1.2)$$

The term "net" is preferred to "partial" because of the well-established usage for "net" (all reactions and efficiencies are partial).

³ Brody, S., *J. Nut.*, 17, 235 (1939).

thermodynamically rather improbable living organisms and related biologic products. This assumed energy cost of morphogenetic "work" may conceivably be of several different categories. First comes to mind potential or "structured" energy, analogous to the energy "structured" into a spring on winding it, or into a storage cell on charging it. The biologist's "action current", and indeed the whole field of electrophysiology, as well as muscular exercise (contraction and relaxation), is based on such charge-discharge phenomena. Bergson⁴ and Terroine and Wurmser^{5,6} suggested that the

Fig. 1.1—Gross energetic efficiency of egg production for fowl of different body weight and different production levels, illustrating the principle of diminishing returns (Ch. 5).

configuration of the formed tissue is on a different energetic level from that of the building-stone precursors.

⁴ Two orders of phenomena are observed in living tissues, *anagenesis* and *katagenesis*. The role of the anagenetic energies is to raise the inferior energies to their own level by assimilating inorganic substances. Henri Bergson, "Creative Evolution", 1907.

⁵ Pour édifier son organisme et le développer, il doit en même temps exercer un travail contre l'extérieur et surtout dans la plupart des cas élever le potentiel chimique des substances dont il dispose. Il y a donc le besoin d'énergie. Terroine, E., and Wurmser, R., "L'énergie de croissance. I. Le développement de l'*Aspergillus niger*". *Bull. Soc. Chim. Biol.*, 4, 519 (1922).

⁶ Cf. Bohr, C., and Hasselbalch, K. A., "Ueber die Kohlensäure production der Huhnerembryos", *Skand. Arch. physiol.*, 10, 149 (1900); "Ueber die Warmeproduction und den Stoffwechsel des Embryos", *Id.*, 14, 398 (1903). Tangl, F., "Beiträge zur energetik der ontogenese", *Pfl. Arch.*, 93, 327; 98, 475 (1903); 104, 624 (1904); 121, 347 (1908); 130, 1, 55 (1909). Joseph Needham, "Chemical Embryology", Cambridge, 1931.

Next comes to mind an example of energy expenditure as is associated with the work of rearranging furniture. Such work is immediately paid for, to entropy, by dissipation of heat to the environment. The potential energy of the room is not increased by such work.

This problem of organization energy is fascinating in its obscurity and controversial implications, physicochemical, biological, and even theological, or metaphysical⁷. It cannot be put to a direct experimental test because, for the second assumption, it is not possible to separate or differentiate the heat of morphogenetic work from the heat of maintenance of the formed tissue⁸. This intriguing problem of organizational energy is discussed in some detail in Chapter 3.

1.4: Basal metabolism, maintenance cost, and efficiency. Living is an expensive process. Circulation, respiration, excretion, and muscle tension never cease while life remains, even under conditions of absolute rest. There are, moreover, energy wastes associated with inevitable activities of enzyme systems in their own right, independently of physiologic usefulness, and there is also an energy cost for maintaining the thermodynamically unstable living state (Ch. 3). These and related processes add up to the large energy cost of maintenance. The minimum energy cost (when the animal is at rest in a thermoneutral environment in the post-absorptive condition), called basal metabolism, is a popular subject for research. The *total maintenance* cost, as contrasted to *basal metabolism*, is not being investigated actively.

Because most feed consumed by animals is expended for basal metabolism and maintenance, we have given the problems considerable attention (especially in Chs. 13 to 15).

The following example illustrates an agriculturally practical aspect of organizational energy as well as of maintenance in relation to time, to energetic efficiency, and even to profit. We estimated mathematically (Ch. 23) that the *net* efficiency of egg production (not including maintenance cost) appears to be of the same order as the net efficiency of milk production; the *gross* efficiency (including maintenance cost, which is proportional to the time involved) of egg production, however, is only about half that of milk production. This difference in *gross* efficiency in the face of equal *net* efficiency may be explained by the greater structural complexity of egg (Ch. 23); there is required relatively more time and consequently relatively more maintenance energy to produce unit egg energy than unit milk energy. The periodic or cyclic nature of the egg-production process, in contrast to the continuous one of milk production, is another factor contributing to the lower gross energetic efficiency of egg production. This exemplifies how organizational complexity may condition in a practical way the gross effi-

⁷ Bergson, *loc. cit.*, and his other books.

⁸ Needham, *loc. cit.*; Tyler, A., *Pub. Staz. Zool. Napoli*, **13**, 155 (1933); *Quart. Rev. Biol.*, **17**, 197 (1942).

ciency of productive processes aside from the energy cost of morphogenesis, a more controversial problem (Ch. 3).

Fig. 1.2—Gross energetic efficiency of milk (F.C.M.) production for cattle of different body weight and different productive levels (see Sect. 5.4).

1.5: Nutritional categories. Productive processes transform input energy, which is food, or “feed” as it is called when used by farm animals, into desired products, milk, egg, meat, work, etc.

The transformation involves several steps. The feed (*gross-energy category**) undergoes digestion, and the digested material (*digestible-energy category*) enters the blood stream or storage organs. Undigested material and fermentation gases are eliminated from the alimentary canal. Some of the *digested nutrients* are eliminated by way of the kidneys; the remainder is *metabolizable energy*. Of the metabolizable energy, part is eliminated as heat increment of feeding ("specific dynamic action", referred to as SDA), the rest is the *net energy category*. Net energy is, then, that part of the total energy which is retained in the body for useful purposes, such as maintenance, growth, milk production, egg production, or muscular work. The fraction of feed energy eliminated in feces, urine, and SDA depends on the balance between nutrients (Ch. 20), on the plane of nutrition (Ch. 5), and on the animal's inherited ability to digest and utilize the feed.

1.6: Organismic and atomistic viewpoints. The energetic efficiency of productive processes depends on many interrelated factors. The specialist investigating one of these factors may be unfamiliar with the methods, aims, and literature of the others. The animal husbandman, however, is (theoretically) a student of the efficiency complex *as a whole*⁹, because the animal is broader than any of the specialized or atomistic fields of knowledge.

The organism is particularly remarkable for its adaptive and regulative (homeostatic) devices adjusting it to fluctuating environmental conditions. Chapters 10 and 25 are concerned with some homeostatic or organismal devices and similar interrelations. Chapter 11 discusses an especially important homeostatic mechanism—body-temperature regulation—and the influence of environmental temperature on the efficiency of biological transformations.

The seasonal temperature rhythm is associated with the seasonal and diurnal light rhythms. Chapters 8 and 9 discuss the relation of these rhythms to productive processes.

Light not only furnishes energy to animals by way of the plant, but also catalyzes many productive processes. Other catalytic processes are discussed in Chapters 6 and 7.

There are individual differences in digestibility¹⁰, metabolizability, and net-energy availability, with corresponding differences in the overall efficiency of the productive process. Of course, digestion itself is a very complex process in which innumerable factors participate, and it is possible that each of these factors is controlled by a separate gene or set of genes. "How many genes may be involved in the development of the reflex stimulating the salivary gland or the secretion of hydrochloric acid in the stomach!"¹³ It is customary to overlook the variability of the individual factors and to

* The gross- and net-energy feed *categories* are not related to the gross and net *efficiencies* (equations 1.1 and 1.2).

⁹ If anyone wishes to search out the truth of things in serious earnest, he ought not to select one special science; for all the sciences are conjoined with each other and interdependent. *Descartes*.

¹⁰ Craft, W. A., and Willham, O. S., "Nutrition and genetics", *Proc. Am. Soc. Animal Production*, p. 260, Nov. 27-9, 1936.

conduct genetic investigations not on the ultimate factors but on complexes, such as inheritance of the complex "growth rate"¹¹, "milk production",

Fig. 1.3—Gross energetic efficiency for horses working at different rates, illustrating the operation of the principle of diminishing returns (Ch. 5).

"egg production", each of which is, of course, the resultant of innumerable interrelated inherited factors.

The productive level is, by definition, directly proportional to the *net-energy* consumed above the maintenance level. It is not directly propor-

¹¹ Palmer, L. S., and Kennedy, C., "Food consumption and efficiency", *J. Biol. Chem.*, **90**, 545 (1931). Morris, H. P., Palmer, L. S., Kennedy, C., "Food requirements for the growth of the rat", Minnesota Agr. Exp. Sta. Technical Bull: 92, 1933.

tional to the *total feed* intake above the maintenance level, because digestibility, metabolizability, and net-energy availability of rations tend to decrease with the feed intake in accordance with the principle of diminishing increments (Ch. 5). Feed intake is, however, an excellent index of the productive aptitude of an animal¹², regardless of the nature of the productive process.¹³ Indeed, there appears to be a good correlation¹⁴ between growth rate in youth and milk-production rate at maturity (both being apparently correlated to the same extent with the feed consumption level); and dairy steers from high-milking dams fatten as efficiently as beef steers¹⁵, high feed consumption being the common characteristic of both.

High productivity is, rightly, sought for, but it should also be realized that it involves certain hazards. Thus, unusually high milk production may result in milk fever and related metabolic disorders, consequences of the inability of the digestive and assimilative systems to keep pace with the demands of the milk-producing apparatus. Long-range hazards of unusually high productive levels may be lessened resistance to infection, circulatory damage¹⁶, and perhaps accelerated senescence (Ch. 18). Extreme muscular effort in hot weather is associated with relatively high mortality of horse and white man. (The less ambitious mule and colored man usually refuse to exert themselves unduly, with corresponding lower hot-weather mortality.)

The highly productive, and consequently highly efficient, animal is such because of a hereditary configuration in which all the participating efficiency factors are developed *harmoniously* for the given high production level. Relative overdevelopment or underdevelopment of one of the vitally participating factors may be catastrophic to the individual or even to the race. Mention was made of milk fever, increased susceptibility to infection, cardiac damage, and early senility as examples of possible hazards of unusually high rates of milk production under certain conditions; of high mortality of horses from "sun stroke" as result of hard muscular work in hot weather; and of high mortality of fowls as result of highly accelerated winter egg production by artificial lighting and feeding (Ch. 23) associated perhaps with nutritional deficiencies (Ch. 20). Other examples will be cited presently (Ch. 7).

There are many individual peculiarities, genetic and environmental, affecting efficiency. Individual farm and laboratory animals—not to speak of humans—differ in their wisdom for selecting diets when offered free choice¹⁷. These may be hereditary or environmental. It is interesting to note that

the growth rate of "superior" individuals is not maximum. By "superior" one¹⁷ means those who are the most efficient users of food and have the highest livability. Contrary to the common belief, the most rapid growth is often

Fig. 1.4—Gross energetic efficiency, Q_o , expended per unit work, Q_{WA} , in horses at different work rates, approaching the absolute expense, Q_A , per unit work, Q_{WA} , as limit (see Ch. 24 for details).

associated with the highest early mortality¹⁷. Very rapid growth may be economical to the animal husbandman by saving overhead maintenance cost but not profitable to the animal whose longevity may be impaired thereby.

It is generally known that there are individual differences in susceptibility to rickets and to nutritional cataract¹⁸, and to cancer induced by estrogens and carcinogens¹⁹.

Neuro-psychiatric peculiarities offer another category of influences on the efficiency of productive processes. Thus animals vary in the amounts of energy they expend for activities un-related to the productive process. Rundquist²⁰ developed two strains of rats which differed in spontaneous activity. We are familiar with the fidgety horse, a "hard keeper", because he wastes so much energy on useless motion, and the placid horse, an "easy keeper". Some of these temperamental differences are due to endocrine peculiarities²¹. Skill in competitive sports, such as running, is, in part, a matter of eliminating useless motions, the result of training as well as heredity.

We thus end this chapter with the introductory statement that the efficiency complex involves innumerable genetic and environmental, physiologic, and economic factors with corresponding difficulties of integration enhanced by the impossibility of saying everything at once. We shall, therefore, break up our efficiency complex into its several components discussed in the following twenty-four chapters.

1.7: Appendix: The following summary of the efficiency equations will be useful as reference in future discussions.

$$\text{Gross* efficiency} = \frac{\text{energy output (as milk, eggs, meat, work)}}{\text{energy input (various categories of feed)}} \quad (1.1)$$

$$\text{Net† efficiency} = \frac{\text{energy output}}{\text{energy input less maintenance energy}} \quad (1.2)$$

Equation (1.1) may be expanded into its constituent components still further:

$$\text{Gross efficiency} = \frac{\text{energy output}}{\text{energy output} + \text{maintenance energy} + \text{other expenses in producing product}} \quad (1.3)$$

Equation 1.3 may be further expanded:

$$\begin{array}{l} \text{Overall or gross} \\ \text{energetic} \\ \text{efficiency} \end{array} = \frac{\text{energy output}}{\begin{array}{l} \text{energy of: (A) product + (B) maintenance + (C) "work",} \\ \text{of organizing precursors into product + (D) increased me-} \\ \text{tabolism of productive system as result of its greater ac-} \\ \text{tivity and of whole body as result of higher hormone and} \\ \text{nutrient concentration in the blood + (E) wastes inci-} \\ \text{dental to transformation of precursors in blood to prod-} \\ \text{uct + (F) maintenance cost of growing product and so on.} \end{array}} \quad (1.4)$$

* Gross energy cost of a process = cost including maintenance.

† Net energy cost = cost not including maintenance.

One might legitimately ask whether the "maintenance" of a productive animal includes item (D) in equation (1.4). The distinction in the denominator of equation (1.4), as between (C) and (F), and between (C) and (D) above, are necessarily arbitrary and subject to criticism, but they serve to illustrate the complexity of the situation.

The apparent efficiency will vary with the category of feed to which the product is compared. The computed efficiency will be greatest if the energy of the product is compared to the *net energy* of the feed, less if compared to *metabolizable energy*, still less if compared to *digestible energy*, and least if compared to *gross energy*.

While from the economic viewpoint the overall or gross efficiency [equation (1.1)] is all-important, from the theoretical viewpoint, the net efficiency [equation (1.2)] may be the more important, because it is not complicated by maintenance (not a part of the productive process), which is dependent on a miscellaneous array of extraneous factors. Because of the basic character of net efficiency, Terroine and Wurmser† termed it "*rendement energetique réel*", that is *real efficiency*, as contrasted to the overall or gross energetic efficiency which they termed "*rendement energetique brut*", that is *crude or apparent efficiency*. During growth, for example, the gross growth efficiency decreases with increasing age, perhaps not because the cost of organization increases, but because the amount of growth *in comparison to the size of the maintenance-expending body* decreases. The importance of the distinction between *gross* and *net* efficiency will become increasingly evident.

Chapter 2

Energetics, Energy Units, and Dietary-Energy Categories*

Science is the attempt to make the chaotic diversity of our sense-experience correspond to a logically uniform system of thought. *Albert Einstein*

2.1: Energetics. Bioenergetics, concerned with energy transformations in living things, is a branch of general energetics generalized by the first and second laws of thermodynamics. We shall discuss these briefly, and then attempt to extend the *thermodynamic form* treatment to the discussion of the several nutrient categories and wastes.

2.1.1: The first law¹, or the *principle of conservation of energy*, asserts that the total amount of energy in an isolated system remains constant. If energy appears at one place, an equal quantity of energy disappears simultaneously in another place; if energy disappears in one form, an equal quantity of energy appears simultaneously in another form. All known forms of energy (mechanical, electrical, magnetic, chemical, etc.) have been converted quantitatively into heat.

The *principle of conservation of matter* is another form of the principle of conservation of energy. Matter and energy are inseparable; according to the theory of relativity and to other considerations², matter and energy are different expressions or measures of the same thing, and they are frequently hyphenated in writing, as *energy-matter*.

The first law is not concerned with mechanisms or rates of energy changes, but only with the initial and final energetic states of the system. It holds true for living as well as for non-living systems: the energy equivalent of work performed by an animal, plus the maintenance energy of the animal, plus

* Grateful acknowledgments are made to Allen E. Stearn, Professor of Physical Chemistry, University of Missouri, for valuable suggestions and for reading the manuscript; also to Professors Henry E. Bent and Earl A. Long of the same department for valuable suggestions.

¹ This first law may be said to have been conceived by Lavoisier, "the father of the science of nutrition", but formulated by Robert Julius Mayer (a physician) in 1842, Herman Helmholtz (a physiologist) in 1847, and substantiated experimentally by James Prescott Joule (a brewer) in 1843 who determined the mechanical equivalent of heat. It is curious that this great generalization of physics is not due to professional physicists: physicists "were tired of futile generalities and anxious to make amends for the wasted time by conscientious factual research" (Epstein, P. S., "Textbook of Thermodynamics", pp. 27-34, 1937).

² Lewis, G. N., *Science*, **30**, 84 (1909). The relation between energy, E , and rest mass, m , is given by the equation $E = mc^2$, in which C is the velocity of light.

the heat increment of feeding must equal the energy generated from the oxidation of nutrients. This definiteness gives the first law a sense of universal finality, and a firm basis for bioenergetic investigations even if the mechanisms of the reactions are unknown.

The first law is usually represented by the equation

$$\Delta E = q - w \quad (2.1)$$

in which ΔE represents increase in the energy content of the system which is equal to q , the heat absorbed from the surroundings (when its sign is positive and heat evolved by the system when its sign is negative), less w , the work done by the system upon the surroundings³.

When work is performed isothermally, $\Delta E = -w$; when heat is transferred without work, $\Delta E = q$.

The concept of change in energy content, ΔE , is usually employed when gases are involved at *constant volume*. At *constant pressure*, it is customary to employ the concept change in *heat* content, ΔH , when equation (2.1) is written

$$\Delta H = q - w \quad (2.1a)$$

For reactions not involving gases, the value of ΔE and ΔH are equal. For reactions involving gases,

$$\Delta H = \Delta E + RT\Delta n = \Delta E + 1.988T\Delta n$$

in which n represents number of mols of the gas, and $R = 1.988 \text{ Cal/}^\circ\text{C}$.

Biologists employ ΔH rather than ΔE because their observations and methods involve constant pressure.

When a reaction occurs reversibly, w is *maximal work*, and ΔE or ΔH is the latent heat of the reaction.

A reaction is said to be *reversible* when it proceeds from stage A to the subsequent stage B in such manner that the energy change is just enough to permit the reversal back from stage B to stage A without loss of energy. When other conditions do not enter to change a situation, natural processes are probably never reversible. This concept of reversibility is, nevertheless, very important in the elucidation of thermodynamic theory, and in man-made system changes, such as in the slow-charging-discharging standard cadmium cell, the concept of reversibility is virtually realized in practice.

As regards the applicability of the first law to animals, many contributions were made beginning with Lavoisier⁴, to whom the modern concept of animal heat is attributed, in 1777, long before the law was formulated. The proof of the applicability of the first law to animals (dogs) is, however, attributed to Rubner⁵, confirmed (on man, working, riding a bicycle) by Atwater and Benedict⁶, and (on cattle) by Armsby⁷.

⁷ Armsby, H. P., "Principles of Animal Nutrition", New York, 1903, and following editions.

The proof consists in comparing the heat of oxidation of nutrients outside and within the body. Outside the body the heat of combustion, ΔH , is determined with an ordinary calorimeter. Within the body, the *nature* of nutrients (carbohydrates, fats, proteins) oxidized is determined from the respiratory quotient and urinary nitrogen (Ch. 12). The *amount* of each nutrient oxidized is computed, with the aid of appropriate factors, from the CO_2 production, O_2 consumption and urinary nitrogen excretion. The heat dissipated by the animal, measured by direct calorimetry, is compared to the computed heat production of the nutrients oxidized. (The heat equivalents of nutrients and their end products are listed in the summary to this chapter.) The observed and computed heat production agreeing to within 1 per cent is taken as proof of the applicability of the first law to animal processes.

2.1.2: The second law.⁸ The first law states that all forms of energy are quantitatively convertible to heat. The second law is concerned with the driving force of reactions, with "chemical affinity", with the losses involved in various reactions, and especially limitations on the conversion of heat into work, that is into energy forms other than heat.

The second law is a statement of the experience that the availability of a given energy form for work is dependent on its tendency to "run down" from its relatively high energy level to the general (lower) level, and that there is a tendency toward equalization of energy levels.

Thus steam can do work not because it is hot, but because it is *hotter* than the environment; compressed air can do work not because it has a high pressure, but because it has a *higher* pressure than the environment, and so on. Heat cannot be employed to do mechanical work if it is equally distributed. Only that fraction of atmospheric heat creates wind (which may run wind-mills) that is distributed unevenly. The heat in the ocean or earth surface is practically unavailable for work because of its practically even distribution. It may, therefore, be said that the total energy of a system is made up of: (1) "bound", unavailable for work, called *entropy*, and (2) "free", available for work. This is one aspect of the second law.

Another aspect of the second law is that only a part of heat energy is convertible to work. This is because work is orderly, relatively large-scale motion, whereas heat is random, uncontrolled, disorderly molecular motion; and it is not possible to convert disorderly into orderly motion of molecules without loss in kinetic energy (heat) of the molecules. Over a century ago (1824) Carnot formulated the equation indicating the maximum heat energy theoretically convertible into work.

Carnot formulated his efficiency equation for heat utilization in an imaginary limiting-ideal engine—one of those scientific fictions so important in the development of science—an engine that is frictionless, does not lose heat and is completely reversible. Carnot's equation is

⁸ The second law, older than the first, was formulated in 1824 by S. N. L. Carnot, a 28-year old French-Army engineer. The modern elucidation of the second law, however, is due to mid-nineteenth-century contributions of Clausius, Gibbs, Helmholtz, Lord Kelvin, van't Hoff and others. For the history, see Lewis and Randall, *loc. cit.* p. 5.

$$w = q \frac{T_1 - T_2}{T_1} \quad (2.2)$$

or in the differential form,

$$dw = q \frac{dT}{T} \quad (2.2a)$$

in which w represents the theoretically maximum work-energy obtainable in the ideal Carnot engine from the heat-energy, q , operating between absolute temperatures T_1 of the boiler and T_2 of the condenser.

Under the usual conditions of about 300° C and 30° C at the boiler and condenser respectively, the ideal Carnot engine converts less than half of the heat, q , into work, w . Ordinary heat engines are, of course, much less efficient.* Only when the lower working temperature is absolute zero (−273° C) would the Carnot engine convert all the heat energy into equivalent work energy. This brings out another aspect of the significance of absolute temperature and its zero. The zero on the absolute-temperature scale may be defined by the temperature at which the Carnot engine is 100 per cent efficient. This idea will come up again in connection with the discussion of entropy and the “third law” of thermodynamics, which defines the absolute zero as the temperature at which entropy is zero for solids.

Although living organisms are not heat engines (life processes are not operated by temperature differences, and the heat produced by the body is the end product rather than the motive power of the body processes as it is in a heat engine), the principle that the efficiency of transformation of one energy-form into another is less than 100 per cent, even theoretically, appears to be as generally true for isothermal chemical processes as for heat engines.

As applied to isothermal chemical reactions, the Carnot equation (2.2) is usually written (Helmholtz’ free-energy equation)

$$\Delta F = \Delta E - T\Delta S \quad (2.3a)$$

or (Gibbs’ free-energy equation)

$$\Delta F = \Delta H - T\Delta S \quad (2.3b)$$

in which, as in equation (2.1), ΔE represents the change in intrinsic or internal energy, and ΔH represents the change in heat content; or more simply, it represents the heat of reaction determined by direct calorimetry or computed indirectly with the aid of Hess’ law† from published thermochemical data‡ of constituent reactions.

* The efficiency, e , of the Carnot engine as given by eq. (2.2) is $e = \frac{T_1 - T_2}{T_1}$.

† Hess’ law, formulated in 1840, is that the heat liberated or absorbed in a reaction is independent of the manner in which the reaction takes place. Thus the heat of formation of CO, not determinable directly, may be estimated from the following equation indirectly: $C + O_2 = CO_2 + 94 \text{ Cal}$; $CO + \frac{1}{2}O_2 = CO_2 + 68 \text{ Cal}$. Therefore, $C + \frac{1}{2}O_2 = CO + 26 \text{ Cal}$.

‡ “International Critical Tables”, McGraw-Hill Book Co., 1929. Landolt, H. H., and Börnstein, R., “Physikalisch-chemische Tabellen”, Berlin, 1923. Lewis and Randall, *loc. cit.*

The symbol ΔF represents the free energy change of the reaction, *i.e.*, the theoretically maximum amount of useful work, analogous to w in Carnot's equation (2.2), obtainable from the ΔH of the process at constant temperature and pressure; and $T\Delta S$ is analogous to the part of the heat in Carnot's equation which is not convertible to work.

The numerical values of the free energies, ΔF , of chemical reactions are extremely useful to students of intermediate metabolism in the animal body, as well as to workers in inorganic, organic, and industrial chemistry for predicting the direction and extent of a chemical reaction. It is a measure of the driving force, of the chemical affinity, of the given reaction. If the standard ΔF has a large negative value (exothermic) the reaction will, when properly catalyzed, take place vigorously and essentially completely; if ΔF has a positive value (endothermic) for a given reaction it will not take place unless supplied with energy from external sources; if ΔF is zero, the system is in equilibrium and no change occurs. Indeed ΔF may be, and preferably is, computed from equilibrium data by the equation

$$\Delta F^\circ = -RT \ln K \quad (2.4)$$

in which K is the equilibrium constant of the given reaction, \ln its natural logarithm, and F° the free energy in a standard state or at unit activity.

In some reactions ΔF may be determined from electromotive-force measurements:

$$\Delta F = -nFE \quad (2.5)$$

in which n is the number of equivalents of chemical change, F the value of the Faraday, and E the electromotive force of the cell.

The characteristic second-law feature in equation (2.3), however, is the term $T\Delta S$, which represents the amount of energy degraded from the free or high-grade form (equivalent to work) to the bound or low-grade form (equivalent to heat) during the process. It corresponds to the wasted heat or bound energy not convertible to work in Carnot's engine [eq. (2.2)].

This increase in bound energy is made up of two factors: capacity, ΔS , and intensity, T (absolute temperature), just as, for example, the work energy of a quantity of heat, q , in steam operating between temperatures T_1 and T_2 is proportional to $q(T_1 - T_2)$.

The *entropy* change in calories per degree (involving simple heat change) is given, for a reversible path, by the equation*

$$\Delta S = \int_{T_1}^{T_2} dS = \int_{T_1}^{T_2} \frac{dq}{T}$$

* When the temperature remains constant, as in fusion, $\Delta S = q/T$, derived directly from the Carnot eq. (2.2). Typical entropy values in E.U. for the standard state: C, 1.3; S, 7.6; H₂, 16; $\frac{1}{2}$ N₂, 23; $\frac{1}{2}$ O₂, 25.

in which dS is the increase in entropy for an infinitesimal change; dq is the infinitesimal amount of heat absorbed; ΔS is the increase in entropy for a finite process. When the temperature is constant (as in fusion), $\Delta S = q/T$.

The numerical value of ΔS of a reaction may be computed from equation (2.3) or, preferably independently, from data on heat capacity and latent heat for a wide range of temperature and, in accordance with the third law, extrapolated to absolute zero and the entropy interpolated at the desired temperature. The equation form used for this purpose is

$$S_T = \Delta S_{(0,T)} = \sum_0^T \frac{C_p}{T} dT + \sum \frac{\Delta H_{tr}}{T_{tr}} \quad (2.6)$$

in which S_T is the entropy at the absolute temperature T , C_p is the specific (molal) heat* at constant pressure, and ΔH_{tr} is the heat of transition (fusion, etc.), or change in heat content of the substance during the transitions which it undergoes in raising its temperature from the absolute zero, 0, to the given absolute temperature, T . As previously indicated, the "third law" provides a measure of absolute entropy by stating that the term S_0 , the entropy at the absolute zero, is equal to zero for systems in equilibrium.

The value of ΔS of a substance may be computed in some cases with the aid of statistical mechanics from spectroscopic data.

The following are illustrative values¹⁰ of ΔH , ΔF , and ΔS at the specified "standard state" or "reference state" of temperature and pressure, in which case the free energy is designated by ΔF° . Unless otherwise specified the "standard state" is assumed to be 25°C (298°K), one atmosphere pressure, and in case of solution one mol per 1000 gm solvent. Each of these conditions, as well as those fixed by these conditions, such as ionization, hydration, solution, etc., affects the thermodynamic values. By way of illustration, consider the oxidation of glucose.

Since the change of H_2O liquid (l) to H_2O gas (g) involves an energy change

$$H_2O (l) = H_2O (g) - 9.7 \text{ Cal (at } 100^\circ\text{C)}$$

it is obvious that the value of ΔH in equation (2.7a) will depend on whether the H_2O is in the l or g state. At 25°C and one atmosphere pressure, when the H_2O is in the l state, CO_2 in the g state and $C_6H_{12}O_6$ in the s (solid) state, equation (2.7a) is written:

That is, $\Delta H = -674$ Cal/mol glucose. (The value of $\Delta F^\circ = -685$ Cal). If the H_2O is in the g state, the value of ΔH would be less by $6 \times 10.4 = 63$ Cal than that given in equation (2.7b). According to Baas-Becking and Parks, the free energy of the reaction under natural conditions when the partial pressure of CO_2 is 0.003 atmosphere is 709 Cal:

* Typical heat capacity at constant pressure, C_p per mol: for $H_2 = 6.5 + 0.0009T$; for O_2 and $N_2 = 6.5 + 0.001 T$.

¹⁰ Taken from Lewis and Randall, *loc. cit.*; Parks, G. S., and Huffman, H. M., "The Free Energies of Some Organic Compounds", New York, 1932; Borsook, H., "Reversible enzymatic reactions", *Ergeb. d. Enzymforschung*, **4**, 1 (1935); Burk, D., "The free energy of nitrogen fixation by living organisms", *J. Gen. Physiol.*, **10**, 559 (1927); *Proc. Roy. Soc.*, **104B**, 153 (1929); *J. Phys. Chem.*, **35**, 432 (1931); Baas-Becking, L. G. M., and Parks, G. S., "Energy relations in the metabolism of autotrophic bacteria", *Physiol. Rev.*, **7**, 85 (1927); Needham, D. M., "Energy-yielding reactions in muscle contractions", *Enzymologia*, **5**, 158 (1938). Stephenson, M., "Bacterial metabolism", Longmans, 1939.

Likewise as regards pressure. In equation (2.7b) it is assumed to be one atmosphere. Under natural conditions of photosynthesis the partial pressures of CO_2 and O_2 are 0.0003 and 0.2 atmosphere, respectively, and $\Delta F = 708$ Cal rather than 685.

The most interesting biological examples illustrating thermodynamic equations are found in the literature¹¹ on the metabolic activities of nitrogen-fixing soil bacteria and, of course, in the recent studies on intermediary metabolism in animals.

Most bacteria are *heterotrophs*; they obtain energy for their metabolic processes by oxidation of carbohydrates [eq. (2.7)] and related organic compounds, as does man. But there are, especially among soil bacteria, many *autotrophs*¹² obtaining energy not from oxidation of organic matter but from oxidation of H_2 , N_2 , S, NH_3 , NO_2 , Fe^{++} , and so on, as illustrated by the following reactions.

$$(\Delta H = -68 \text{ Cal/mol H}_2; \Delta F^\circ = -56 \text{ Cal})$$

$$(\Delta H = -142; \Delta F^\circ = -119)$$

The *nitrosomonas* or nitrite producers obtain energy by oxidation of ammonia to nitrites:

The *nitrobacter* or nitrate producers obtain energy by oxidizing nitrites to nitrates:

The above are exothermic reactions. The formation of ammonia from atmospheric nitrogen is endothermic.

$$\Delta H = +82 \text{ Cal}; \Delta F^\circ = +79 \text{ Cal}$$

The energy for the endothermic formation of NH_3 is obtained from the exothermic oxidation of such carbohydrates as glucose which yield 700 Cal free energy per mol, more or less depending on conditions [eq. (2.7b)]. Theoretically, therefore, one mol glucose furnishes sufficient free energy, ΔF , to convert about 4 mols N_2 to NH_3 . Actually, however, not one but 30 to 50 mols glucose are required to furnish the needed energy, the "machine efficiency"¹¹ of the process is only 2 to 3 per cent.

Practically, therefore, the value of ΔF is no better indicator of the "machine" efficiency of a reaction than is the value of w in the Carnot equation (2.2). Living organisms, like engines, have irreversible heat losses due to various causes which in organisms go under the name of "maintenance", and these "maintenance" losses, therefore, tend to be inversely proportional to the speed of the process. There is a time element affecting the irreversible losses.

The value of ΔF , as previously explained, is the best measure of the chemical affinity, the driving force of spontaneous reactions.

¹¹ Burk, D., *J. Gen. Physiol.*, **10**, 559 (1927); *Proc. Intern. Cong. Soil Sci.*, **3**, 67 (1930); Baas-Becking and Parks, *loc. cit.*

¹² Winogradsky, S., *Ann. Inst. Pasteur*, **4**, 213, 257, 760 (1890); *Id.*, **5**, 92, 577 (1891).

As a matter of fact, however, reactions in biologic systems are not "spontaneous" in the sense that this expression is used in relation to inanimate systems. Biological reactions are mostly *coupled*¹³. Even the conversion of sugar to alcohol and carbon dioxide may be considered as a coupled reaction. The part of the molecule which is oxidized to CO₂ (exergonic¹⁴) is coupled with and furnishes energy to the part converted to fatty acid or alcohol (endergonic¹⁴).

The following fermentation or glycolysis reactions may also be considered as examples of *internal oxidation-reductions* not involving external (molecular) oxygen:

The fermentation of glucose to produce lactic acid (glycolysis) is an important method of supplying energy to animal tissues when the oxygen supply for normal oxidation energy is inadequate as in violent exercise and in cardiorespiratory insufficiency due to disease. It is, therefore, of great importance in intermediary metabolism. Microorganisms produce in their metabolism a great variety of incompletely oxidized products, a few of which are listed below. Many of them, such as alcohol, acetic acid, citric acid, oxalic acid, kojic acid, gluconic acid, fumaric acid, and so on, are of very great importance.

(Phosphocreatine hydrolyzes during muscle contraction and resynthesizes during recovery.)

¹³ Cf. Borsook¹⁰, Burk¹⁰, Kolcekar, H. M., "The nature of energetic coupling in biological syntheses", *Chem. Rev.*, **28**, 71 (1941).

¹⁴ Coryell, C. D., [*Science*, **92**, 380 (1940)] suggested that the terms *exothermic* and *endothermic* be confined to heat changes, ΔH ; *exergonic* and *endergonic* be used for designating ΔF changes (*ergon*, from Greek, meaning work).

It should perhaps be re-emphasized in conclusion that we have not been concerned with the internal energy, E , of systems but merely with heat-content changes, ΔH ; free-energy changes, ΔF ; and entropy changes, ΔS . Thus ΔH , the heat of formation of CO from C and O₂ or the heat of combustion of C to CO (under standard conditions) is -26 Cal; likewise, the heat of formation of CO₂ from CO, or the heat of combustion of CO to CO₂, is -68 Cal. We are concerned not with total energy but with changes or increments for well-defined reaction stages under well-defined conditions.

Similarly the molal heat of formation, ΔH (at 25°C and 1 atmosphere pressure) of formic acid from its elements, C, H₂, and O₂, is -100 Cal and corresponding free energy, ΔF , is -85 Cal; the heat of combustion, ΔH , of formic acid to H₂O and CO₂ is -63 Cal, and so on for other compounds as given in the literature.

Another factor needing re-emphasis is that environmental conditions such as temperature, pressure, but especially concentration of reactants and products, influence to a greater extent the free energy, ΔF , that is the theoretically maximum work derivable from the energy, than they do the heat-content change, ΔH . The application of this observation is of the greatest practical agricultural importance, especially as it relates to plane of nutrition, which we shall discuss throughout the book. The simple illustration was already cited that in the reaction

the values of both ΔH and ΔF are -94 Cal per mol when the oxidation is done under a pressure of one atmosphere O₂ and CO₂. But when the partial pressure of CO₂ is 0.0003 atmosphere and of O₂ 0.2 atmosphere, the value of ΔF = -99 Cal, whereas ΔH is still -94 Cal.

Finally, an important but apparently mysterious equation needs to be clarified. It was already noted that the work, w , by an expanding gas from volume v_1 to v_2 against a pressure, p , is proportional to $p(v_2 - v_1)$:

$$w \propto p(v_2 - v_1)$$

This proportionality is generalized (when p has always its equilibrium value $\frac{RT}{V}$) to the less evident* equality

$$w = -RT \ln (v_2/v_1) \quad (2.8)$$

in which R is the gas constant (1.988 gm-cal or 0.082 lit-atm) and \ln is the natural logarithm (2.303 times the common logarithm) of the given ratio.

Likewise, it may be shown that the free-energy, ΔF , accompanying the dilution of a solution from concentration c_1 to c_2 isothermally is given by the second-law equation form

$$\Delta F = -RT \ln c_1/c_2 \quad (2.8a)$$

This equation form is used for computing kidney work in concentrating urine against a higher osmotic pressure, for electromotive force developed between different ionic concentration, c_1 and c_2 , and so on. The free-energy change, $-\Delta F$, equivalent to the work of concentration of urine from blood by the kidney is given¹⁵ by the equation

* The derivation: $\int_{v_1}^{v_2} p dv = \int_{v_1}^{v_2} RT/v dv = RT \int_{v_1}^{v_2} dv/v = RT \int_{v_1}^{v_2} (\ln v_2 - \ln v_1) = -RT \ln v_1/v_2$.

¹⁵ For numerical illustration see Borsook, H., and Winegarden, H. M., *Proc. Nat. Acad. Sci.*, 17, 3 (1931).

$-\Delta F = nRT \ln \frac{C_{\text{plasma}}}{C_{\text{urine}}}$ in which n is the molar concentration in the urine excreted during a given interval. Similarly the work of transporting water from plasma to urine is $-\Delta F = nRT \ln \frac{n_{\text{plasma}}}{n_{\text{urine}}}$.

Turning to more general considerations, the meaning of the definition of the second law, that the difference in energy potentials tend to come to a dead level, is exemplified by daily experiences: when bodies of different temperatures are brought together, the temperatures become equal, thermodynamic equilibrium is established, and the energy becomes useless for work performance.

Statistically viewed, when molecules moving at different speeds (that is, when the bodies are at different temperatures) are brought together, they collide in accordance with the theory of probability, and a compensation of velocities, or thermal equilibrium, is established. Considered in this way, entropy is a condition of maximum probability (Boltzmann). It is improbable that heat will be transferred from a colder to a warmer body, just as it is improbable for a river to rise above its source. Both thermodynamic laws are common-sense laws, with many analogies and implications, yet not without apparent contradictions, two of which may be noted.

The definition of entropy as condition of maximum probability, maximum energetic levelling, maximum disorganization, and so on, all imply a "running down of the universe", an implication which raises the following question often asked by children to whom this concept is explained: if the universe is running down, it must have been previously "wound up". Who wound it up? How was it wound up? What was the "first cause" and the cause of this cause of this winding up?

A second apparent contradiction concerns the evolution of complex organisms from simple and the growth and development of complex bodies from apparently simple eggs (Ch. 16). While there is a tendency toward levelling, yet there are many integrative, directive, creative and individuating activities illustrated by evolution of species, growth and development of individuals, or even by the writing of an orderly book from disorderly data and thoughts.

The fact is that we are not aware of all the factors operating at the living organizational level which may, conceivably, have selective mechanisms analogous on the molecular level to "Maxwell's demon". Probability predictions (Boltzmann derived the second law on statistical considerations) are known to be upset by "thought" (leading to action) with which the living are endowed.

This apparent contradiction may, perhaps, be rationalized, in harmony with Boltzmann's statistical derivation of the second law, by saying that biologic phenomena are relatively local and that general statistical laws need not apply to local events. The limitation of the second law has no significance

for single molecular events. Intelligent purposive action may interfere with the normal operation of probability. Thus life insurance tables for the United States do not necessarily reflect the life expectation in a local community living up to unusually high health standards, especially for its children. Improbable events may occur locally in accordance with the calculus of probability and, of course, by proper coupling with external energy-yielding systems. It was noted¹⁶ that biologic syntheses, for example, are normally coupled between two reactions, one representing an increase in free energy, $+\Delta F_1$, the other a decrease, $-\Delta F_2$, and that the absolute value of ΔF_2 is larger than of ΔF_1 . This way one system is more highly organized (entropy lowered) at the expense of simultaneous disorganization (entropy raised) in an interrelated system. In the more familiar example of refrigerating machines heat is raised from a colder to a hotter body; but, of course, by performing work on the system at the expense of external energy. The overall result of such operation is a net increase in entropy, a decrease in free energy. There is philosophic questioning concerning the applicability of the second law to living systems¹⁷, but, as illustrated by the following examples, there is no reason for practical questioning from the standpoint of the present book.

It is sometimes said, and with truth, that the agricultural industry is the only one (with the exception of those utilizing water and wind power) engaged in increasing the supply of free energy for man's use with the aid of green plants, the "great anabolizers", by the basic photosynthetic process

thus supplying the chemical energy for the basic catabolic process

This photosynthetic process involves a local increase in free energy, a local decrease in entropy. But from the viewpoint of the system as a whole, this geobiologic increase in free energy is coupled or linked with the solar decrease in free energy, and the thermodynamic efficiency of photosynthesis is not very high even theoretically.^{18, 19} There is an increase in entropy of the

¹⁸ Borsook¹⁰, p. 39.

¹⁹ Cf. Transeau, E. N., "The accumulation of energy in plants", *Ohio J. Sci.*, **26**, 1 (1926): The earth receives about one two billionth of the sun's energy. Of this part received, about 35 per cent is reflected into space, 65 per cent absorbed. Of this absorbed part, 0.12 per cent enters into the life cycle. Of this 0.12 per cent, about 24 per cent is utilized by agricultural plants. Of the 24 per cent utilized by agricultural plants, the plant stores 1 to 25 per cent, some 75 per cent of the energy utilized by the plants being

system as a whole; the law of degradation of energy definitely holds. Organisms, however, capture and transform much of the energy that would otherwise be lost.

It may similarly be said that farm animals are wasteful converters of feed into milk, eggs, meat. Thus man obtains about 1500 Cal of useful energy by consuming a pound of grain directly but only about 300 Cal (20 per cent) by consuming milk produced at the cost of a pound of grain (Ch. 21), or about 150 Cal (10 per cent) by eating meat (Ch. 3) or eggs (Ch. 23) produced at the cost of a pound of grain. These animals are, however, humanly useful because they utilize feeds which man cannot or does not wish to utilize directly.* Draft animals have an overall energetic efficiency of about 10 per cent, 90 per cent of the free energy being wasted (Ch. 24). The same is true of inanimate machines, humanly useful but energetically wasteful. In brief, while humanly useful, productive processes involve overall free energy losses: the entropy tends toward a maximum, the free energy to a minimum.

In the case of plant growth, the radiant energy of the sun would be lost anyway, so that whatever photosynthetic use is made of this energy by man is a gain, although the utilization of the energy is low; likewise, while farm animals are wasteful in their utilization of roughage energy, yet whatever utilization is made by the animals for productive purposes is total gain to man who cannot himself consume roughage. Loss and gain are thus relative terms depending on the viewpoint.

2.2: Energy units and energetic equivalents. Equivalent quantities of different forms of energy yield equal quantities of heat (first law). All forms of energy may, therefore, be represented in heat units, Calories or British thermal units (Btu), as indicated in the appendix to this chapter.

While living organisms are not heat engines, it is customary to express the energy exchange in heat units because work energy and storage energy in animals are measured by calorimetric methods, in heat units.

The heat units commonly employed are the *small or gram-calorie*, the heat required to raise the temperature of one gram of water 1° C at 15° C; the *large or kilogram-calorie*, the heat required to raise the temperature of one kilogram of water 1° C, written with a capital C; *mega-calorie*, equivalent to 1000 Cal or 1,000,000 cal, which is Armsby's *Therm*. The Btu is the heat

used for its maintenance. The overall efficiency of the photosynthetic process is thus extremely small, although the thermodynamic efficiency of the photosynthesis may be 80 per cent. Warburg, O., *Z. physikal. Chem.*, **106**, 191 (1923). See also Spoehr, H. H., *J. Ind. Eng. Chem.*, **14**, 1144 (1922). Holsberg, C. L., *Id.*, **6**, 524 (1924); Briggs, G. E., "Energetic efficiency of photosynthesis in green plants", *Proc. Roy. Soc.*, **105B**, 1 (1929). Wurmser, R., *Ann. d. Physiol.*, **1**, 47 (1925). Adams, E. Q., *J. Am. Chem. Soc.*, **48**, 292 (1926).

* It is said [*Brit. Med. J.*, **2**, 269 (Aug. 2, 1941)] that the protein mainstay of the German Army is not meat but "bratting", a soybean-skimmilk sausage; that, likewise, peanut and cottonseed meal (after the oil has been extracted therefrom), usually fed to cattle, is at present used in Germany as a meat substitute in the form of sausage, etc., at, perhaps, 10 per cent of the cost of meat. Soybean is, of course, a staple in China.

required to raise the temperature of 1 lb of water 1° F. A Calorie (kg-cal) is thus about 4 Btu (3.9681 Btu) or 1 Btu is equivalent to about $\frac{1}{4}$ Cal (0.2522 Cal).

2.3: Feed and nutrient energy categories. There appears to be some analogy between the thermodynamic energy categories discussed in section 2.1 and the feed and nutrient categories discussed in this section.

Thus the energy equivalent of the oxygen consumed (about 5 Cal/lit) by a working animal above that consumed at rest is analogous to what was called ΔH in section 2.1, the total energy associated with the work, and the maximum theoretically obtainable work by the animal is analogous and, perhaps, close to what was termed free energy, ΔF , in section 2.1.

Fig. 2.1—Ratio of CO_2 to CH_4 in the rumen of cattle and goats.²¹

We shall discuss four feed and nutrient categories: *net energy*, sometimes called “production energy”, equivalent to Kellner’s “starch values”; *metabolizable energy*; *digestible energy* or TDN; *gross energy*.

The *net-energy* category formulated and defined by Armsby²⁰ as the maximum proportion of the feed energy convertible to work, milk, egg, meat, and maintenance seems to correspond to the free energy, ΔF , of thermodynamics, although the latter is confined to the theoretically maximum (not actual) energy convertible to work, and not to storage (as for milk production).

²⁰ Armsby, H. P., “The Principles of Animal Nutrition”, 1903; “The Nutrition of Farm Animals”, 1917; “Net Energy Values for Ruminants”, Penn. State College Bull. 42, 1916. See also Fraps, G. S., “Practical applications of productive energy values to problems concerning feeds and feeding”, *Proc. Am. Soc. Animal Production*, 1937; “The production coefficients of feeds”, *Texas Agr. Exp. Sta. Bulls.* 185 (1916), 203 ('16), 329 ('25), 373 ('28), 402 ('28), 436 ('31), 454 ('32), 461 ('32).

The analogy, here as elsewhere, between nutrient and thermodynamic categories is only formal.

The *metabolizable-energy* (or physiological fuel value) category, defined by Armsby²⁰ as the net energy plus heat increment of feeding, seems to correspond to change in the heat content, ΔH , of thermodynamics.

The heat increment (above the postabsorptive level) associated with the nutritive process, usually called "specific dynamic action", or *SDA*—which

Fig. 2.2—Time curves, following feeding, of methane percentage and methane volume in expired air of goats (see also Fig. 12.8 b, p. 323).

might be called food-utilization tax—appears to be analogous to the entropy term, $T\Delta S$, of thermodynamics.

And just as we have the basic thermodynamic equation

$$\Delta F = \Delta H - T\Delta S \quad (2.3)$$

so we may write

$$NE = ME - SDA \quad (2.10)$$

in which *NE* is the net energy, *ME* is the metabolizable energy, and *SDA* the specific dynamic action or the heat increment of feeding. This analogy is closer for work processes than for maintenance and storage, to which the net energy concept also applies.

The other two feed categories are *gross energy*, which is simply the combustion value of the original feed or food; and *digestible energy* which is the gross energy less the fecal energy.

The gross-energy category has no important nutritional significance since it gives no clue to the nutritional value of the feed. Thus the gross energy (combustion value) per unit weight is practically the same for dry starch as for dry wood, despite the fact that starch is utilized completely by the body, whereas the wood is not utilized at all.

While the *digestible-energy* category is much more significant nutritionally than gross energy, it is also ill-defined. The so-called digestible energy, defined by the difference in combustion value of the feed and feces, is not really, but only apparently digestible, since the feces contain not only indigestible material but also voluminous excretions from the body proper into the digestive tract and secretions of juices and enzymes by the digestive-tract wall, as well as abrasions from the walls and a rich flora of bacteria and, in cattle especially, a fauna of protozoa. The *metabolic* part of the feces (not part of the undigestible feed or food) is highly variable depending on the amount of roughage in the ration, plane of nutrition, balance between nutrients and so on.

Moreover, some species, such as ruminants, produce anaerobically (by fermentation) enormous quantities of gases which have a high caloric value. These gases, not being part of the feces, are consequently classed with the digestible nutrients!

The most voluminous gases in the rumen are²¹ CH₄ and CO₂, but there are also said²² to be H₂, H₂S, and CO (Fig. 2.4). Fatty acids are also formed.²¹

It is difficult to determine the ratio of CO₂ to CH₄ because the fatty acids formed in fermentation liberate CO₂ from carbonates. We obtained data on the CO₂/CH₄ ratios *as they exist* in the paunch of cattle, goats, and sheep at various times after feeding; as well as percentages of methane in expired air, as shown in Figs. 2.1 and 2.4. These data enabled us to estimate that the average well-fed dairy cow produces about 300 liters per 24 hours of each fermentation product,²³ CH₄ (Fig. 2.4) and CO₂. Assuming that the energy equivalent is 9.5 Cal/lit for CH₄ and 4 Cal/lit for CO₂, the fermentation-energy loss is about 4000 Cal/day,²⁴ equivalent to about a third of the resting maintenance energy cost of a 1200-lb cow (Ch. 15).

²¹ Washburn, L. E., and Brody, S., "Methane, hydrogen, and carbon dioxide production in the digestive tract of ruminants", Univ. Missouri Agr. Exp. Sta. Res. Bulls. 263, 1937, and 295, 1939.

²² Olson, T. M., "Ruminant gases", *J. Dairy Sci.*, **25**, 684 (1942).

²³ See, also, Cole, H. H., Mead, S. W., and Kleiber, M., "Bloat in Cattle", Calif. Agr. Exp. Sta. Bull. 662, 1942.

²⁴ According to Rossini [*J. Research*, **6**, 49 (1931)] the molar heat of combustion of CH₄ at 25°C and one atmosphere is 212.8 Cal.

The fermentative production of fatty acids, methane, and CO_2 in the rumen may be variously represented, as

after Krogh and Schmit-Jensen²⁵, involving a 3 to 1 proportion between the volumes of CO_2 and CH_4 ; or it may be imagined to occur as follows²⁶:

The above discussion indicates a great loss of feed energy in the form of fermentation gases. The loss may not, however, be as great as it seems, because the fermentation losses appear to come from the indigestible part of the ration, or the fermentation loss is compensated by greater digestibility

Fig. 2.3—The time course of gas formation after green alfalfa feeding (Cole, *et al.*).²³

associated with the fermentation process. This is indicated by the fact that the percentage of metabolizable energy of a given ration is the same for cattle and rabbits (Figs. 5.3 and 5.4), despite the great difference in fermentation gases produced by these two species.

The *metabolizable energy*, or *physiologic* fuel value, category in nutrition (eq. 2.10) corresponds to the heat change, ΔH , in thermodynamics (Section 2.1). The *physiologic* fuel value of nutrients, especially of nitrogenous nutrients, is considerably below that of the *bomb-calorimeter* fuel value, ΔH , because the *oxidizing powers of the body* are below those of the bomb calorimeter. Thus protein is not completely oxidized in the body: for each gram of protein catabolized about 1.3 Cal are excreted in the urine in the form of in-

²⁵ Krogh, A., and Schmidt-Jensen, H. O., "The fermentation of cellulose in the paunch of the ox and its significance in metabolism experiments", *Biochem. J.*, **14**, 686 (1920).

²⁶ Barker, H. A. [*Arch. Mikrobiol.*, **7**, 404, 420 (1936)] reported methane production by bacteria, thus: $\text{CO}_2 + 2\text{C}_2\text{H}_5\text{OH} \rightarrow \text{CH}_4 + 2\text{CH}_3\text{OH}$. The alcohol or similar compound acts as the H donor for reducing CO_2 .

completely oxidized products such as urea, creatinine, and so on, thus reducing the bodily oxidation value of protein to 4.35 Cal/g, or 1973 Cal/lb from the calorimeter-combustion value of about 5.65 Cal/g or 2563 Cal/lb. Less conspicuous urinary energy losses are incurred by other nutrients. Moreover, as previously noted, gas production in the digestive tract involves losses of

Fig. 2.4a—Time course of composition of rumen gas in Jersey cow 831²¹ following feedings of alfalfa hay; grass; alfalfa hay and grain.

partly oxidized products. It will be shown in Chapter 5 that the metabolizable-energy category, obtained by deducting these losses from the digestible-energy category, is about 85 per cent of the *TDN* (digestible-energy category) in cattle and about 93 per cent of the *TDN* in rabbits, the exact percentage depending on the plane of nutrition, balance between nutrients, and especially the amount of fermentable material fed.

The *net-energy* category in nutrition corresponds to the free-energy change, ΔF , in thermodynamics. Armsby²⁷ built his famous cattle-respiration calorimeter for the purpose of measuring this *net-energy* category of nutrients.

Fig. 2.4b—Time course of composition of rumen gas in Jersey cow 831²¹ after feeding of grass.

Unfortunately, it is more difficult to evaluate the net energies of feeds than the free energies of chemical reactions. The *net-energy* category has not, therefore, come into practical use in the feeding of farm animals. Instead

²⁷ Armsby, H. P., "Nutrition of Farm Animals", 1917.

the *digestible-nutrient* category, termed for short *TDN*, is commonly used in the feeding of farm animals.²⁸

$TDN = \text{digestible carbohydrates} + \text{digestible protein} + \text{digestible fat} \times 2.25.$

The conversion of weight units, such as grams or pounds *TDN*, or metabolizable nutrients, or net-energy nutrients, to Calories offers difficulties. The

Fig. 2.4c—Time course of composition of rumen gas in Jersey cow 831²¹ after a feeding of alfalfa hay and grain.

average heats of oxidation of the three principle foodstuffs in a bomb calorimeter are estimated²⁹ to be:

Carbohydrates	4.10 Cal/g	1860 Cal/lb
Fats	9.45 Cal/g	4287 Cal/lb
Protein	5.65 Cal/g	2563 Cal/lb

²⁸ Morrison, F. B., "Feeds and Feeding", 1936, presents extensive *TDN* tables.

²⁹ Fries, J. A., U. S. Dept. Agr. Bureau of Animal Industry, Bull. 94, 1907. Armsby, *loc. cit.* Atwater, W. O., and Bryant, A. P., "The chemical composition of American food materials", U. S. Dept. Agr. Bull. 28, 1903. Benedict, F. G., and Atwater, W. O.,

It must be emphasized that there are very wide variations in individual determinations.²⁹

The convention had developed among students of human nutrition³⁰ to multiply the grams carbohydrate in the diet by 4, the grams of the protein in the diet by 4, and the grams of fat in the diet by 9, and assume that the result represents the *physiologic* fuel value (metabolizable energy Cal) of the

Fig. 2.4d—Time course of composition of rumen gas in Jersey cow 831²¹ after a feeding of alfalfa hay.

diet. The difference between these 4:4:9 physiologic-fuel factors and 4.10:5.65:9.45 bomb-calorimeter conversion values previously cited is assumed to represent the dietary losses in the urine (energy of creatinine, urea,

C., "Chemistry of Food and Nutrition", Macmillan, 1938. Landolt and Bornstein, *loc. cit.* "International Critical Tables", *loc. cit.* Maynard, L. A., "Animal Nutrition", 1937.

³⁰ Sherman, H. C., *loc. cit.*; Chatfield, C., and Adams, G., "Compilation of American food materials". U. S. Dept. Agr. Circular 549, 1940.

etc., amounting to about 1.3 Cal/g protein), feces (assumed 2 per cent loss for carbohydrates, 5 per cent loss for fats and 8 per cent loss for proteins), and fermentation gases.

There is no agreement for the conversion of animal feeds to metabolizable energy. Some authors estimate the metabolizable-energy values in ruminants by assuming that they produce 4.5 g CH₄ per 100 g digested carbohydrate, and that this CH₄ together with the associated CO₂ has a thermal equivalent of 60 Cal per 100 g, or 273 Cal per lb, of digested carbohydrate³¹; and that the urinary energy in cattle is between 4 to 5 per cent of the gross feed energy (Ch. 5). Armsby³² reported (for cattle) metabolizable values of 1600 Cal (1500–1700) per pound *TDN* for roughages, 1830 Cal (1720–2200) for concentrates, and 1660 Cal (1580–1870) for mixed rations. Christensen and Hopper³³ reported (for sheep) 1670 Cal for roughages and 1690 Cal for mixed rations. Forbes and Kriss³⁴ reported 1690 Cal metabolizable energy per pound *TDN*, or about 3.6 Cal per g *TDN*. In the interest of uniformity the writer suggested³⁵ that the *TDN* be converted to Calories by multiplying g *TDN* by 4, or lbs *TDN* by 1814, or oz *TDN* by 113.4. The resulting caloric values would represent, roughly, the metabolizable energy of the *TDN*. The conversion factor 4 Cal/g *TDN* is somewhat too high for ruminants and somewhat too low for omnivores and carnivores. In any case, the given conversion factor is a rough estimate, and its relation to the actual metabolizable energy necessarily depends on the nature of the ration and in ruminants on the amounts of rumen fermentation. To avoid complications with consequent misunderstandings, we say that our efficiency-computations in this book will be based in most cases with respect to consumed *TDN*, assuming that 1 g *TDN* is equivalent to 4 Cal or 1 lb *TDN* to 1814 Cal.

The above considerations make it evident that the apparent efficiency of a biologic process, as defined by equation (1) (Ch. 1) depends on the nutrient category used as reference base [denominator in eq. (1)]. The apparent efficiency is greatest when employing the net-energy category in the denominator as reference base, and least when employing the gross-energy category. For muscular work, the efficiency with respect to the *net-energy* category is represented by the rate of oxygen consumption of work above rest, thus:

$$\text{Net efficiency of work} = \frac{\text{work accomplished in Cal. equivalents}}{\text{oxygen consumed at work above rest in Cal. equivalents}}$$

³¹ Kellner, [*Landw. Vers.-Stat.*, **53**, 415 (1900)] reported 4.2 to 4.3 g CH₄ per 100 g carbohydrates digested. Armsby ("Nutrition of Farm Animals", p. 638) reported 4.8 g CH₄ for roughages and 4.7 g for concentrates.

³² Armsby, H. P., "The Nutrition of Farm Animals", p. 278. See also Penn. State College Bull. 42, 1916, on "Net Energy for Ruminants".

³³ Christensen, F. W. and Hopper, T. H., "Digestible nutrients and metabolizable energy in certain silages, hays, and mixed rations", *J. Agr. Res.*, **67**, 477 (1938).

³⁴ Forbes, E. B., and Kriss, M., *Proc. Soc. Animal Production*, p. 1131 (1931).

³⁵ Brody, S., "Report of the conference on energy metabolism", National Research Council, Washington, 1935.

If the Calorie equivalent of oxygen consumed is replaced by the Calorie equivalent of the total feed consumed, the apparent efficiency will be only 50 per cent of that when oxygen is used as reference base, since the net energy of herbivor's feed is about 50 per cent of the gross energy.

2.4: Summary and appendix. Section 2.1 discusses the principles of thermodynamics and their relation to biology and especially to agriculture. The thermodynamic uniqueness of the agricultural industry is that it increases the local available free energy (or decreases the entropy) for man's use by utilizing the solar radiant energy which would otherwise be lost. It appears that, with one or two exceptions, all other human activities lower the local free-energy³⁶ reservoir. This explains the national importance of agriculture in general and of soil conservation in particular, since soil is the basic national resource, the thread that binds us, by way of plants, to the source of all energy, the sun.

Some attention is given to the philosophic aspects of the applicability of the principle of degradation of energy to such constructive processes as growth, development and evolution of organisms. An attempt was made to bring out formal analogies between nutrient and thermodynamic categories.

The following symbols and definitions were used in Section 2.1.

- ΔE : Change in internal energy of a system during a process. ΔU is often employed synonymously with ΔE .
- ΔH : Change in heat content associated with a process, as in the heat of combustion or heat of formation. This includes pressure-volume energy as indicated by the relation $\Delta H = \Delta E + \Delta(PV)$ and by $\Delta H = \Delta E + P\Delta V$, in which $\Delta(PV)$ represents change in pressure volume product and $P\Delta V$ is work done by or upon the system.
- Carnot Cycle: a theoretical sequence of operations converting heat at a higher temperature, T_1 , to work plus heat at a lower temperature, T_2 .
- ΔS : Change in entropy, in bound energy, in low-grade energy, in randomness, not convertible to work.
- ΔF : Change in free energy, which is capacity to do work or in the theoretically obtainable maximal useful work from the reaction at constant pressure and temperature. $\Delta F = \Delta H - T\Delta S$ is the fundamental thermodynamic equation for a process at constant pressure and temperature corresponding to Carnot's equation for a process involving a temperature gradient. (When there is also pressure-volume work, the maximum work including this pressure value is represented by ΔA , and $\Delta F = \Delta A - P\Delta V$.)
- T : Absolute temperature = Centigrade temperature, t , $+273^\circ$.
- K° : Absolute temperature scale (named after Lord Kelvin) for which the zero is -273.1°C .
- \ln : Natural logarithm, 2.3026 times the common logarithm.
- e : Base of natural logarithms, 2.71828.
- F : Faraday = 96,500 coulombs = 23.07 Cal
- q : Heat absorbed [eq. (2.1)].
- w : Work done [eq. (2.1)].

³⁶ Cf. Ostwald, Wilhelm, "Der Energetische Imperative", Leipzig, 1919. The imperative reads, "Waste not free energy, treasure it and make the best use of it". In 1886 Boltzmann expressed the same idea: "The struggle for existence is a struggle for free energy".

- R:** Gas constant = 1.987 Cal/degree = 8.31507 joules/degree = 8.31507 volt-coulombs.
- n:** Number of equivalents or mols involved.
- C_p:** Heat capacity at constant pressure per mol.
- C_v:** Heat capacity at constant volume per mol.
- QO₂:** c.mm. of O₂ taken up per mg dry tissue per hour; QCO₂: = c.mm CO₂ given out per mg dry tissue per hour.

Section 2.2 discusses the energy units employed in agricultural bioenergetics, especially as they relate to farm animals. It is suggested that the kilogram-calorie, designated by Calorie with a capital C, be employed as the basic unit. Armsby's *Therm*, or mega-calorie, is 1000 Calories. The following conversion table shows several interrelations.

(See following pages for caloric equivalents.)

Section 2.3 discusses the four feed and nutrient energy categories: net energy, metabolizable energy, digestible energy and gross energy, also the heat increment of feeding (*SDA*) and the fermentation, urinary and fecal energy losses.

SDA: "Specific dynamic action", the heat increment of feeding above the post-absorptive level. It is analogous to the entropy term, $T\Delta S$, in thermodynamics.

N.E.: Net energy is the gross energy (combustible energy of the original material) less the fecal, urinary, fermentation-gas, and *SDA* energy. It is the energy convertible into the maximum amount of work, milk, egg, meat, etc. It is analogous to the free energy term, ΔF , in thermodynamics.

M.E.: Metabolizable energy is *N.E.* plus the *SDA*. $N.E. = M.E. - SDA$. It is the gross energy less the fecal, urinary and fermentation energy. It is analogous to the ΔH term in thermodynamics.

D.E.: Digestible energy is gross energy less fecal energy.

TDN: Total digestible nutrients = digestible carbohydrates + digestible protein + digestible fat $\times 2.25$. 1 g *TDN* is estimated to be roughly equivalent to 4 Cal/g or 1814 Cal/lb. The exact value depends on species, plane of nutrition, balance between nutrients and other factors, and is, therefore, subject to correction and even debate. The average *calorimetric*-combustion values are, however, fairly definite, about 4.1 Cal/g for carbohydrates, 5.6 for protein and 9.4 for fat.

It will be shown in Chapter 5 (Fig. 5.4) that empirical observations on cattle yield the following energy values for the several categories.

	Gross energy of feeds (heat of combustion)		Digestible energy		Metabolizable energy (physiological fuel value)		Net energy of feed	
	(Cal/g)	(Cal/lb)	(Cal/g)	(Cal/lb)	(Cal/g)	(Cal/lb)	(Cal/g)	(Cal/lb)
Cattle	4.5	2000	3.2	1600	2.7	1200	2.2	1000
Rabbit	4.5	2000	2.9	1300	2.7	1200	2.3	1000

	Digestible energy, % of gross	Percentage values		Net energy, % of gross	digestible	metabolizable
		Metabolizable energy, % of gross	% of digestible			
Cattle	71	60	85	49	69	81
Rabbit	64	60	93	51	79	85

In general, the heats of combustion of nutrients vary directly with the hydrogen and carbon content, and inversely with the oxygen content, roughly

Approximate Combustion Values, Cal/g

Carbon	8	Succinic acid [$C_2H_4(COOH)_2$]	3.0
Hydrogen	34.5	Oxalic acid [$(COOH)_2$]	0.668
Sulfur	3.2	Citric acid ($C_6H_8O_7$)	2.478
Methane	13.3	Lactic acid ($C_3H_5O_2COOH$)	3.66
Ethyl alcohol (C_2H_5OH)	7.07	Urea (CH_3ON_2)	2.528
Glycerol [$C_3H_5(OH)_3$]	4.3	Creatinine ($C_4H_7N_3O$)	4.6
Glucose ($C_6H_{12}O_6$)	3.75	Creatine ($C_4H_9O_2N_3$)	4.24
Sucrose ($C_{12}H_{22}O_{11}$)	4.0	Uric acid ($C_5H_4O_2N_4$)	2.74
Lactose ($C_{12}H_{22}O_{11}$)	4.0	Glycin ($C_2H_5O_2N$)	3.11
Starch ($C_6H_{10}O_5$)	4.2	Tyrosin ($C_9H_{11}O_2N$)	5.915
Acetaldehyde (CH_3CHO)	6.12	Alanine ($C_3H_7NO_2$)	4.35
Acetic acid (CH_3COOH)	3.49	Urinary nitrogen substances in	
Propionic acid (C_3H_5COOH)	4.96	rats on casein diet: 3.059 Cal.	
Butyric acid (C_4H_7COOH)	5.95	equivalent to 6.67 lit. O_2 or 5.47	
Palmitic acid ($C_{16}H_{32}O_2$)	9.35	lit CO_2	
Stearic acid ($C_{17}H_{35}COOH$)	9.53	Wood, sugar, charcoal	8
Oleic acid ($C_{18}H_{34}O_2$)	9.5	Gluten	6
Tributyrin ($C_{18}H_{36}O_6$)	6.4	Hemoglobin	5.9
Olive oil	9.4	Casein	5.7
Hog fat	9.5	Egg yolk	8.1
Sheep fat	9.5	Egg albumin	5.7
Butterfat	9.2	Muscle	5.7

*Heats of Combustion of Nutrients or Feeds**

	Heats of combustion in terms of several common units					Elemental Composition			
	Cal/g	Cal/kg	Cal/lb	Cal/oz	Therms/ 100 lbs	C %	H %	O %	N %
Starch and glycogen	4.1	4200	1905	119	190.5	44	6.2	49

Average cattle and rabbit ration	4.5	4500	2040	128	204				

* Conversion factors used: 1 kg = 1000 g = 2.205 lbs = 35.274 oz.; 1 lb = 16 oz = 453.6 g = 0.4536 kg; 1 oz = 28.35 g. See preceding reference, Sherman, Morrison, Maynard, and others for sources of data.

in proportion to the combustion values of hydrogen, carbon, and oxygen as indicated in the following table. (The heat of combustion of hydrogen in Cals/g is 34.5; carbon 8.08; sulfur, 3.2; methane, 13.35; ethyl alcohol, 7.07; the heat equivalent of oxygen is 2.6 to 3.4 Cal/g or 4.7 to 5.1 Cal/liter). The average heat of combustion of carbon in tissue is assumed to be the same as in glucose, 113 Cal per gram atom of carbon.

The following tables list additional illustrative values of heats of combustion of nutrients, feed stuffs, and several familiar substances and other equivalent values used in this book.

Table of Energetic Equivalents

Metabolic water from nutrients

100 g protein yields 41 g H_2O
 100 g fat yields 107 g H_2O
 100 g CH yields 60 g H_2O

Heat equivalent of O_2 and CO_2

1 liter O_2 = 5.14 Cal for glycogen
 4.4 Cal for oils (cottonseed, cod liver, corn, etc.)
 4.6 Cal for fat (as butterfat)
 4.6 Cal for protein
 5.06 Cal for starch
 5.08 Cal for sucrose
 4.8 Cal for hay
 22.4 lit. O_2 = 30 g glycogen.
 1 lit. O_2 = 5 Cal (5.05 at R.Q. 1.0, and 4.69 at R.Q. 0.70, and 4.825 at R.Q. 0.82)
 = app. 15,500 ft-lbs (15,580 to 14,470) = 2134 kg-m (2155 to 2001).
 1 lit. CO_2 = 5 to 6.7 Cal (5.05 at R.Q. 1.0, and 6.7 at R.Q. 0.70).
 1 g CO_2 = 2.5 to 3.4 Cal (2.57 at R.Q. 1.0, and 3.41 at R.Q. 0.70).
 1 g O_2 = 3.5 Cal (3.53 at R.Q. 1.0, and 3.28 at R.Q. 0.70).
 (Note: At 0° C 760 mm pressure and 45° lat. 1 lit. CO_2 = 1.9652 g;
 1 lit. O_2 = 1.4292 g; 1 lit. air = 1.2928 g; 1 lit.
 water vapor = 0.8038 g; 1 g water vapor = 1.2440 liters).

Calories

1 Cal = 1 kg-cal = 1000 gm-cal = 3.968 Btu at 60° F = 4185 joules
 = 3086 ft-lbs = 426.7 kg-meters
 1 cal = 1 gm-cal = 4.185 Joules = 42670 g-cm = 41.3 cc-atm = 0.04133 lit-atm
 1 Btu = 0.252 Cal at 15° C = 778 ft-lbs

Work units (force \times distance)

1 ft-lb = 0.1382 kg-met = 0.000324 Cal = 0.001286 Btu = 0.0005 ft-tons
 1 kg-meter = 7.233 ft-lb = 0.002344 Cal = 0.009298 Btu
 1 hp-hour = 1,980,000 ft-lbs = 641.3 Cal
 1 joule = 0.2423 Cal = 10,000,000 ergs = 10,198 gm-cm = 0.00987 lit-cm

Power units, units work per unit time

1 hp (horsepower) = 33,000 ft-lbs per minute (or 550 ft-lb/sec or 1,980,000 ft-lbs
 per hour
 = 4562.4 kg-m per minute
 = 746 watts = 0.746 (about 3/4) kilowatt
 = 2.1 liters oxygen/min = 10.7 Cal/min = 642 Cal/hr
 watt = work at the rate of about 1/4 Cal/sec
 kilowatt = 101.9 kilogram-meters per second
 = 737.56 foot-pounds per second
 = 1000 joules per second = 10,000,000,000 ergs per sec
 = $\frac{1}{0.746}$ = 1.34 hp
 1 kg-m/sec = 9.81 watts
 watt-hour = 0.85968 Cal
 kw-hour = 859.68 Cal = 3412 Btu
 1 lit-atm = 10.333 kg-m = 74.73 ft-lbs = 101.32 joules = 24.207 cal = 0.09607 Btu

Chapter 3

Energetic Efficiencies of Growth and Work Processes

Waste not free energy; treasure it and make the best use of it. *Wilhelm Ostwald*

While there is no sharp dividing line between the two, it is convenient to divide agriculturally productive processes into two general classes (1) work and (2) growth, including "growth" of fat, milk, egg, wool, etc.

Thus defined, "growth" means the constructive or assimilatory synthesis of one substance at the expense of another (nutrient) which undergoes dissimulation. This is only one definition of growth; others will be considered in Chapter 16. In thermodynamic terms, the energetic efficiency of growth is the ratio of the growth *work* performed to the free energy expended. Traditionally, however, the energetic efficiency of growth is defined by the ratio of energy stored in the organism by the nutrient energy consumed.

3.1: Energetic efficiency of muscular work and the maintenance complication. Equation (2.2) indicates that the theoretically maximal efficiency of the Carnot heat engine is, under the usual temperature conditions, about 50 per cent. The maximal efficiency of actual heat engines is up to 20 per cent for steam engines, up to 25 per cent for gas engines, and 40 per cent for diesel engines. The average efficiencies are, of course, below maximal estimates.

Animals, however, operate not by virtue of changes or differences in temperature and pressure, as do heat engines, but by chemical energy operating at constant temperature and pressure, and the efficiency of isothermal converters, as of some electric transformers, approaches 100 per cent under certain conditions. Thus the efficiency of a slow-charging and discharging cadmium standard cell is almost 100 per cent [eq. (2.5)]. Furthermore, the free energy, ΔF , of the major body fuel, glucose, is practically identical with its heat of oxidation, ΔH , at constant temperature and pressure [eqs. (2.7a) and (2.7b)]. The efficiency of muscular work might, therefore, be expected to be much higher than that of a heat engine.

Actually, however, the *maximal* efficiency of muscular work in our horses, after deducting the "wastes" for maintenance and walking without load, was observed to be no higher than the *maximal* efficiency of the Carnot engine, not over 40 per cent (Ch. 24).

We measured *work performance* in horses by the method illustrated in Fig. 24.1 (p. 901), by multiplying the weight pulled, W , by the distance pulled, and the *energy expenditure* of these horses by the rate of oxygen consumption, assuming that virtually all energy was obtained by oxidation of glucose, as no doubt it was. The energy from the glucose thus oxidized [eq. (2.7)] is the heat of reaction, ΔH , which as previously noted is virtually identical with its free energy, ΔF .

No work was expended for moving the treadmill, which was actuated at desired speeds by an electric motor.

The energy expended by the animal included the following items:

1. Work accomplished
2. "Basal metabolism"
3. Heat increment of feeding (*SDA*)
4. Standing, above that of lying
5. Walking without load, above that of standing
6. Overcoming internal resistance (viscosity of muscle colloids)
7. Overcoming external resistance (wind, contact of feet with ground, etc.)
8. Useless incidental movements associated with pulling
9. Additional internal work of circulation, respiration, excretion, muscle tension, etc.
10. "Recovery" processes (see Ch. 6)

To simplify matters, we measured the oxygen consumption during: (A) standing, which covers items 2, 3, and 4; (B) walking without load, item 5; and (C) pulling the load, item 1. Item 10 was insignificant under the given conditions.

We then had three categories of efficiency:

$$\text{Gross (or total)* efficiency of work} = \frac{\text{useful work accomplished (Cal)}}{\text{O}_2 \text{ consumed (Cal)}} \quad (3.1)$$

$$\text{Net (or partial)† efficiency of work} = \frac{\text{useful work accomplished (Cal)}}{\text{O}_2 \text{ consumed during work above that of rest (Cal)}} \quad (3.2)$$

$$\text{Absolute efficiency of work} = \frac{\text{useful work accomplished (Cal)}}{\text{O}_2 \text{ consumed during work above that of walking at the same speed without load (Cal)}} \quad (3.3)$$

The oxygen consumed in Calories, of course, corresponds to ΔH in thermodynamics.

It is obvious that the value of the gross efficiency [eq. (3.1)] will depend on the speed of work. The longer the time taken for performing a given quantity

* The term "gross" is preferred to "total" efficiency in order to avoid the implication that we are dealing with "total" energy changes.

† The term "net" is preferred to "partial" because of the well-established usage for "net" (all reactions and efficiencies are in a sense partial).

of work—that is, the longer the time of holding the muscles in a state of unproductive tension—the greater the overhead maintenance cost (items 2 to 4 above). On the other hand, the greater the speed of work, the greater the energy cost of the moving muscles in overcoming the internal resistance of the viscous colloids which make up the body. The gross efficiency of muscular work as a function of speed must, therefore, be of a rising and declining type (Fig. 24.3, p. 904) as it is for such machines as automobiles (Fig. 24.4, p. 905).

The speed or time factor also affects the net [eq. (3.2)] and absolute [eq. (3.3)] efficiency because the energy expenditure for overcoming the internal resistance of the body colloids differs with speed. Speed of work affects the efficiency in animals in a manner somewhat analogous to that of temperature and pressure on the free-energy values of chemical reactions, or on the work efficiency of Carnot's engine.

It is important to note, on the basis of the data in Chapter 24, that for given physiologic work levels the efficiencies, gross, net, and absolute, are the same in (large) Percheron horses, (small) Shetland ponies and (still smaller) men. At a given *physiologic age and condition* the efficiency of work is independent of the size of the animal.

The observed maximal efficiency of muscular work in horses on treadmills will be shown in Chapter 24 to be of the order of 25 per cent for gross efficiency [eq. (3.1)], 28 per cent for net efficiency [eq. (3.2)], and 35 per cent for absolute efficiency [eq. (3.3)].

Fenn¹, and Hill and associates², reported efficiency computations of a different but related kind. Hill's computation on the theoretical maximum muscular work efficiency is based on the consideration of the energetics of an isolated frog-muscle strip. Hill imagines a reversible cycle—similar to the *PV* or Carnot cycle—in which the maintenance and related elements do not enter as complicating factors. Under such theoretical conditions, the "theoretical maximum work" was computed to be about 40 per cent approximately the same as for the Carnot engine.

Of this 40 per cent theoretical efficiency perhaps 60 per cent is, according to Hill, actually recoverable as work. What becomes of the remaining theoretically recoverable 40 per cent work energy? Hill thinks it is expended in overcoming the internal resistance of the body colloids. This resistance is wasteful of energy, but is useful to the animal because without it, he would "tear his tendons, break his bones, 'pull' his muscles, strain his joints".

Fenn computed a maximum gross work-efficiency of 23 per cent from data on the running of a man (carrying himself—no external load as in our horses). The work performed when running at maximum speed was computed to be at the rate of 2.95 hp and energy expended at the rate of 13 hp. Of the 13 hp expended 7.8 hp (60 per cent) was estimated to represent "waste of recovery", and 5.2 hp (40 per cent), "initial" (anaerobic) phase of muscle contraction. 2.95 hp of the "initial" energy (22.6 per cent of the total 13 hp or 57 per cent of the "initial" 5.2 hp) was used for work apportioned as follows: 1.68 hp (56.9 per cent of the 2.95, or 12.9 per cent of the 13 hp) for acceleration of limbs; 0.67 hp (22.7 per cent of 2.95, or 5.2 per cent of 13 hp) in friction of foot with ground; 0.10 hp (3.4 per cent of 2.95, or 0.77 per cent of 13 hp) for overcoming gravity; 0.13 hp (4.4 per cent of 2.95, or 1 per cent of 13 hp) in wind resistance. Unlike Hill, Fenn

¹ Fenn, W. O., *Am. J. Physiol.*, **90**, 343, 1929; **92**, 583, 1930; **93**, 433, 1930.

² Furusawa, K., Hill, A. V., and Parkinson, J. L., *Proc. Roy. Soc.*, **102B**, 28, 43, 380 (1927-8).

attributes much of the energy loss to overcoming external rather than internal viscosity resistance. Unlike Fenn's and Hill's running men, our working horses incurred no appreciable oxygen debt, so that Fenn's theoretic computations are not quite applicable to our working-horse data. None the less, these figures should be suggestive.

A basic difference between the work of an animal and of an engine is that the animal expends energy even when not working. The all-day or all-life energetic efficiency of an animal is, therefore, a complex function, among other factors, of the percentage of time spent for the work. The energy cost of maintenance tied up with the time factor is, aside from the economic aspects, a central problem in biology and agriculture which, necessarily, will frequently come up in this book, in various guises.

3.2: Energetic efficiency of growth and the maintenance complication.

The growth-process category of biologic transformations is largely in the nature of storage: in higher animals and man the proteins, carbohydrates, fats, minerals, and vitamins in the diet are transformed into body, milk, egg, and so on, containing the same or derived substances. The situation is more complex in the case of bacterial and plant growth. The purely storage aspect of growth may be of no particular thermodynamic interest, but there is probably a *work* aspect to growth which is of thermodynamic interest.

Thus, the growth process involves creation and maintenance of: internal surfaces, differences in electromotive potentials, and differences in osmotic pressure, especially such as are involved in secretion, excretion, absorption, and in general transformation of amorphous nutrients to complex organisms. The configuration of the living organism, as for example, the newly-hatched chick, is on a quite different physico-chemical level from that of the yolk, white, and shell from which the chick developed, and it is, therefore, reasonable to assume that growth includes a work component involved in changing the configurations from that of food to that of organism.

In addition to the "work-of-growth" component, there are many irreversible free-energy losses which may be lumped together under the heading of "maintenance cost". Life is, so to speak, a flame, and simultaneously with the growth, building-up, process, there is a continuous oxidation, levelling, or catabolic process as predicted by the second law of thermodynamics. This "maintenance cost" is, perhaps, in part at least, the price paid for maintaining the thermodynamically unstable and statistically improbable complexly living, growing, evolving configuration, in the face of the opposite tendency of levelling disorganization to increase in entropy, as predicted by the second law of thermodynamics. Here speed of growth, size of body which has to be maintained, age on which speed and body size depend, and liberated catabolic enzymes enter as complicating elements in the estimation of the work of growth.

3.2.1: Efficiency of growth of bacteria: yeasts: and molds. The energetic efficiency of growth of bacteria, especially of autotropic bacteria, is surpris-

ingly low. Burk³ reported a gross efficiency of about 3 per cent for the bacterial conversion of atmospheric nitrogen to ammonia. Meyerhof⁴ reported an efficiency of about 6 per cent for the assimilation of carbon from CO₂ (by *nitrobacter*) with the energy obtained from oxidation of nitrites to nitrates. Meyerhof's computations on the basis of the observed N/C ratio and assumption that the bacterial-body carbon has a combustion value of 113 Cal per gram atom of carbon (the same as in glucose, which according to Parks is 118 Cal per gram atom) was substantiated by Baas-Becking and Parks⁵ on the basis of free-energy considerations. These authors also worked over Ruhland's⁶ data with respect to the free-energy efficiency of bacteria which obtain their energy for reducing CO₂ into body tissue by oxidizing hydrogen. The efficiency of this assimilation is among the highest, about 26 per cent. (Eight mols H₂ are oxidized for the reduction of 1 mol CO₂; $\text{H}_2 + \frac{1}{2}\text{O}_2 = \text{H}_2\text{O}$, $\Delta F_{298} = -56$ Cal; the assimilation of 1 mol CO₂ to C₆H₁₂O₆ requires 118 Cal, $\frac{1}{6}$ of 709, see eq. (2.7c). Therefore, the efficiency is $\frac{118}{56 \times 8} \times 100 = 26$ per cent.)

As previously explained, the gross efficiency of growth of bacteria, as of other organisms, tends to increase with the speed of growth, since the major proportion of irreversible energy loss is associated with what is called "maintenance", a tax which must be paid regardless of whether or not the organisms grow. Thus, according to one observation⁷, whereas during the first 10 days of growth of bacteria, when growth was most rapid, the gross efficiency was about 20 per cent, the growth efficiency during a 30-day period was 12.5 per cent because the organisms made very little growth in the last 20 days although the maintenance expense continued. Similar results were reported by Rubner⁸ and others on other species of bacteria.

The gross energetic efficiency of yeast growth appears⁹ to be of the order of 10 per cent, the exact value depending on the rate of growth.

Rubner¹⁰, who was particularly interested in the influence of body size on maintenance cost, observed that the energy cost of maintenance, in terms of Calories per day per gram body nitrogen, is 1.0 for an adult man, 3.0 for a child, 3.0 for a dog, 15 for a mouse, 17 for a sparrow, and 20 to 60 for common bacteria, depending on species, temperature and so on. Other conditions being equal, the smaller the organism, that is, the greater the ratio of surface area to weight, the higher the maintenance cost per unit weight.

A possible objection to Rubner's reasoning as it relates to bacteria is that dead bacteria may have as great a "maintenance cost" as live ones, because

as indicated by Buchner's¹¹ epochal discovery, cell-free bacterial extracts ferment sugar, and bacterial cultures always contain a large proportion of dead and autolyzing cells and considerable concentrations of the bacterial enzymes. Buchner's discovery, incidentally, marks the beginning of the modern era of enzyme chemistry. In brief, the fermentation speed is not necessarily a function of the bodily need, or indeed even related to the body, but varies with enzyme concentration, often liberated on the death of the organism.

It is possible that similar purposeless irreversible free-energy losses occur in bodies of higher organisms, a sort of tax to entropy, similar to that on conversion of heat to work in a heat engine. It is, at any rate, doubtful that the basal metabolism is simply the work of the physiological processes, such as that of circulation, respiration, secretion, excretion and muscle tonus. The energy expenditure for blood circulation under basal conditions is variously estimated from 5 to 15 per cent of the total; for excretion (kidney), 5 per cent of the total; for respiration, up to 15 per cent. Krogh¹² estimates that the energy for the functional activities made under basal conditions amount to about 25 per cent of the total metabolism. How is the remaining 75 per cent of the basal energy expended?

Brown⁹ reported the interesting observation that the heat production of a population of non-growing yeast is about 100 times that of an adult man of equivalent mass; and that growing yeast generates considerably less heat per unit substrate fermented than do non-growing. This indicates the danger of extrapolating maintenance values from non-growing to growing organisms. Moreover, it may be illogical to do so because "maintenance" properly refers to a steady state, whereas growing organisms are not in a steady state.

The energetic efficiency of growth of molds is, apparently, much higher than that of bacteria and yeast. Terroine and Wurmser¹³ reported a gross efficiency (including maintenance) of about 60 per cent, of the same order as of the chick and silk-worm embryos (see below) in contrast to an efficiency of 10 to 30 per cent for bacteria and yeast. The greater efficiency of molds may be attributed to more rapid growth and to greater control of catabolic enzyme activity. On the other hand, this difference may be due to methodologic research differences. While bacterial and yeast cultures contain a high concentration of catabolic enzymes liberated by autolyzing and perhaps living cells, the mold mycelia are harvested quantitatively before they autolyze. If a method were employed for harvesting bacteria and yeast cells prior to their loss or excretion of catabolic enzymes, the efficiency of the two might be the same.

¹² Krogh, A., "The respiratory exchange of animals and man," p. 58, 1916.

¹³ Terroine, E., and Wurmser, R., *Bull. Soc. Chim. Biol.*, **4**, 519 (1922).

The net efficiency (not including maintenance) of mold growth was estimated by Terroine and Wurmser to be about 72 per cent. But, as for yeast and bacteria, one may question the significance of maintenance as obtained on a non-growing organism in relation to the maintenance cost of a normally growing one.

3.2.2: Energetic efficiency of prenatal growth. The bird, insect, or fish embryo is particularly suited for growth efficiency investigations because of the complete control of the organism, the definiteness of the nature of the nutrients, and the convenient relative isolation (Needham calls it cleidoic or closed-box system) from complicating environment. The gross energetic efficiency of growth of the chick up to hatching is obtained by estimating the combustion values of: (1) the egg, (2) the newly-hatched chick, and (3) the unused part of the egg, such as the left-over yolk and membranes.

Such measurements on the energetic efficiency of embryonic growth of the chick, silk worm, and fish were made by Tangl¹⁴ and his pupils. Tangl's aim was to investigate what he termed *Entwicklungsarbeit*, the "work" of growth and development.

As in the case of bacterial growth, the gross efficiency, including maintenance, is easily determined, as indicated by the following example.

Combustion value of a hen's egg.....	87 Cal	100%
" " " hatched chick.....	38 Cal	43%
" " " unused material (yolk, membranes, etc.)..	26 Cal	30%
Energy lost during incubation.....	23 Cal	27%

The gross efficiency is, then, $\frac{38}{38 + 23} \times 100 = 62$ per cent. The energy

loss is $\frac{23}{38 + 23} \times 100 = 38$ per cent. How shall one explain the loss of the 23 Cal, or 27 per cent? According to Tangl, the 23 Cal represent the *Entwicklungsarbeit*, "work of development". This cannot be entirely true, because at least some of it must have been used for maintenance, and there is no simple method for differentiating the maintenance from the work components.

The following efficiency computation based on silk-worm data¹⁵ yields very similar results.

Combustion value of a batch of unincubated silk-worm eggs	71.402 Cal	100%
" " " hatched larvae.....	31.879 Cal	44.65%
" " " unused material.....	22.291 Cal	31.22%
Energy lost during incubation.....	17.232 Cal	24.13%

Total efficiency, $\frac{31.879}{31.879 + 17.232} \times 100 = 65$ per cent;

energy loss, $\frac{17.232}{31.879 + 17.232} \times 100 = 35$ per cent.

¹⁴ Cf. *inter alia*, Tangl, F., *Pflüger's arch.*, **93**, 327 (1903). Tangl, F., and Farkas, K., *Id.*, **104**, 624 (1904). Tangl, *Id.*, **130**, 1, 55 (1909). For a comprehensive review, see Needham, J., "Chemical Embryology," vol. 2, Cambridge University Press, 1931.

¹⁵ Farkas, K., *Pflüger's arch.*, **98**, 490 (1903).

Since the finished chick embryo is about 50,000 times the size of the silk-worm larvae, these two sets of data furnish an opportunity for comparing the influence of body size on the gross efficiency of embryonic growth of large and small embryos.

From the foregoing tables of Tangl and Farkas,

	Chick (%)	Silk-worm (%)
Energy loss during incubation.....	27	24
Gross efficiency, assuming that unused material did not participate in the growth process.....	62	65

Thus, the gross efficiency of embryonic growth is of the order of 60 to 65 per cent.

To equalize species differences with respect to weight, the efficiencies may be computed in terms of unit dry weight, as follows:

For the chick embryo, from Tangl,¹⁵ we have

Combustion value of chick embryo..... 5.77 Cal/g dry weight
Energy lost during incubation..... 3.50 " " "

Gross efficiency of chick growth..... $\frac{5.77}{5.77 + 3.5} = 63$ per cent

For the silk-worm embryo from Farkas, we have

Combustion value of silk worm..... 5.33 Cal/g dry weight
Energy lost during incubation..... 3.10 " " "

Gross efficiency of silk-worm growth..... $\frac{5.33}{5.33 + 3.10} = 63$ per cent

The above comparison indicates that in spite of the size and species difference between chick and silk worm, there is no significant difference in gross efficiency of the two.

Similar efficiency values may be obtained from data on frogs¹⁶

Combustion value of frog embryo..... 5.5 Cal/g dry weight
Energy lost during incubation..... 5.3 " " "

Gross efficiency of frog-embryo growth..... $\frac{5.5}{5.5 + 5.3} \times 100 = 51$ per cent

and on the sea urchin.¹⁷

Combustion value of *Fundulus heteroclitus* embryo..... 4.8 Cal/g dry matter
Energy lost during incubation..... 3.3 " " "

Gross efficiency of embryo growth..... $\frac{4.8}{4.8 + 3.3} \times 100 = 59$ per cent

It is instructive to note that the fuel value per gram dry substance of chick embryo increases in sigmoid fashion from 5.1 Cal at the fifth day of incubation to 6.2 Cal at the end of the incubation period (21 days). The fuel value of dry unincubated egg-and-white mix is 6.94 Cal per gram.¹⁸ This is a

¹⁸ Needham, "Chemical Embryology," vol. 2, p. 964.

cogent argument against the use of increase in "dry matter" as index of growth in energy.

It is significant that while gross energetic efficiency per gram dry matter is the same for the *finished* embryo in chick and silk-worm, there are changes in the efficiency during the period of growth, as indicated by the following table from Needham¹⁸ based on Tangl's data on the chick.

Age (days)	3	5	7	9	11	13	15	17	19
Gross efficiency (%)	43	44	47	49	56	66	66	66	67

Needham explains this rise in efficiency (1) by possible decline of basal metabolism per unit weight with increasing weight, as inferred from Rubner's law; and (2) by extrapolation of Miss Stephenson's recapitulation theory to the effect that the enzymes are brought under continuously increasing control of the organism during ontogeny with consequently increased "disciplined" processes.

Instead of increased "discipline" growth, the apparently lower energetic efficiency in early embryonic life may reflect a greater speed of morphogenesis involving a greater work-energy component in comparison to the weight increment.

There is some confusion concerning the nature of this work energy of morphogenesis and growth. It may become resident in the formed structures, a species of configurational energy analogous to the energy stored on winding a spring. But existence of such configurational energy is somewhat hypothetical, since it is apparently not possible to measure it convincingly. Needham¹⁸ has discussed the literature on this hypothetical organizational energy and appeared to conclude that it amounts to 4 per cent of the growth transaction. Bohr and Hasselbalch¹⁹ reported that during the first few days of incubation of the chick embryo, heat was absorbed rather than dissipated, or at any rate, that there was a low heat production in comparison to oxygen consumption. This apparently "missing heat" may be due to endothermic reactions, to the retention of "organization energy" in the tissues²⁰. Rapkine²¹ observed unusually high respiratory quotients which he interpreted as indicating synthesis by coupled oxidation-reduction reactions as contrasted to simple combustion.

The situation is summarized in Section 1.3. For the present it may be noted that Tangl's research ignored the possibility that the energy expended for the "work" of growth and development may be structured in the tissue as potential energy (analogous, for example, to the energy expended for charging a battery or winding a spring); it assumed, on the contrary, that the energy expended for the "work" of growth and development is expended

¹⁸ Bohr and Hasselbalch, see ref. 6, Chapter 1.

²⁰ Terroine, E., and Wurmser, R., *Bull. Soc. Chim. Biol.*, **4**, 519 (1922); Meyerhof, O., *Biochem. Z.*, **35**, 280 (1911).

as heat analogous to that expended for rearranging the chairs in a room, in which case the potential energy of the chairs or room is not increased. Tangl, accordingly, measured the developmental energy by the difference in caloric values of the substrate (egg) and of the formed tissue (newly hatched chick, or silk worm, or fish). The heat thus measured by Tangl, however, included not only (1) the work of developing the organism, but also (2) the work of maintaining the organism. The net result of Tangl's work is that we are still ignorant of the magnitude of the organizational energy, since there is no method for separating (1) from (2) above.

The evidence seems to favor the viewpoint that much of the energy expended for organization is dissipated in the form of heat, as Tangl tacitly assumed, rather than structured into the organism. This may be inferred partly from the fact that unlike the structured energy in a battery or spring, the energy of differentiation is not reversible; differentiation processes are not reversible. Moreover, the energy in the formed tissue has not been shown to be higher than that of its constituent amino acids, carbohydrates and fats.

Several other sets of data substantiate the idea that much, if not all, of the organization energy is dissipated rather than structured. Thus, the pubertal-growth acceleration in children is associated with a metabolic acceleration²². The basal heat production in adult convalescent patients tends to parallel the speed of gain in weight during convalescence²³. Rapidly growing rats (speed of growth controlled by litter size²⁴ and also by changing age²⁵) have a much higher oxygen consumption or heat production—regardless of the reference base employed—than slowly growing rats. Rapid morphogenesis is associated with rapid metabolism.²⁶ The high basal heat production of adolescent children may, however, be attributed to a flare-up of high endocrine activity at that time. The high oxygen consumption of patients convalescing from emaciating diseases, or of rats on a high plane of nutrition, may be attributed to the latter factor (*SDA*, etc.) rather than to extra thermodynamic work of growth.

Tyler's²⁷ and Collier's²⁸ results are more convincing. Tyler reported that the oxygen consumption or energy liberation by the differentiating sea urchin varies with the amount of differentiation. Thus, the total oxygen consumption of two half-sized embryos up to the end of gastrulation is greater than of one normal-sized embryo. The two half-sized dwarf embryos are assumed

by Tyler to expend the same amount of energy for maintenance and growth as one whole embryo. The difference in energy expenditure is assumed to result from the extra differentiation work involved in developing two embryos. similar results were obtained by other methods of increasing developmental rates.

Collier reported an 85 per cent increase in oxygen consumption at the peak of regeneration of the fasting worm *Tubifex tubifex*. Here the plane of nutrition did not enter as a complicating factor, as all animals were fasted. Measurements made of the oxygen consumption of intact and regenerating animals of the same size and in the same condition showed that there was an 85 per cent increase in oxygen consumption at the peak of regeneration. The obvious interpretation is that the extra oxygen consumption represents the "machine work" of regeneration.

3.2.3: Energetic efficiency of postnatal growth. It is not possible to measure the energetic efficiency of postnatal growth with the precision obtained on prenatal growth of the chick, because of the many variables influencing postnatal growth, such as differences in muscular activity, food supply and feeding habits, nature and quantity of food especially balance between nutrients, environmental temperature, and so on. There are, moreover, economic difficulties in making balance sheets of income and outgo of energy and especially determination of the composition of the gains.

Farmers estimate what they call efficiency—really a reciprocal function of efficiency—by the amount of feed consumed for making a given gain in weight. The terms "amount of feed" and "amount of gain" are poorly defined since the energetic equivalence of availability of feed and the energetic equivalent per unit body weight gain are highly variable. There is an enormous amount of such rough-and-ready data in the agricultural experiment stations. The following are a few illustrations of efficiency estimates for postnatal growth.

It is instructive to quote, by way of introduction, Rubner's²⁹ "law" of growth, to the effect that the amount of energy required for doubling the birth weight is the same per kilogram in all species, except man. About 4800 dietary Cal are required to construct a kilogram of normal body substance containing 30 g nitrogen and 1720 Cal. The energetic efficiency of the early postnatal growth is thus $1720/4800 \times 100 = 35$ per cent. The following is an example of Rubner's computations: Cal in the gain, 1500; Cal for maintenance, 2500; therefore, the energetic efficiency of growth is $1500/(2500 + 1500) = 37$ per cent.

Rubner evidently refers in this example to what we call *net energy* of the feed. Indeed, he makes no mention of the feed used—only the energy in the gain and the (roughly estimated) energy cost of maintenance. The

²⁹ Rubner, M., "Das Problem der Lebensdauer und seine Beziehungen zu Wachstum und Ernährung," 1908.

efficiency would, of course, be much lower if the energy in the gains were divided by the energy in the food consumed, and this value would vary with the feed category employed—gross, digestible, metabolizable, or net. To indicate the differences obtained by two comparable investigators, one may cite Lusk³⁰, who reported that pigs retain 20 per cent of their dietary calories during the first doubling of body weight, whereas Rubner stated that 40 per cent of the ingested energy is retained. Lusk reported the combustion value of the gain as 866 Cal per kilo, whereas Rubner stated that the combustion value of the gain as 1722 Cal per kilo. Yet, both Lusk and Rubner seem to agree that the milk energy required for a pig to double its birth weight is about twice the amount of energy deposited in the body.

Attention should be directed to Kleiber's reasoning for assuming, as does Rubner and Lusk, that when other conditions are equal, productive efficiency is independent of body weight. According to Kleiber³¹, the ratio of feed consumption to basal metabolism and maintenance is independent of body weight, and, therefore, the excess feed that may go for productive processes is independent of body weight. Thus the ratio of available calories ingested to basal metabolism is 4.4 in chicks, 4.2 and 5.6 in steers and 5.0 in a rabbit. In support of this, Kleiber³² cited data³³ showing that 820-lb cattle and 114-lb sheep make the same gains per unit feed consumed during a 60-day period. The daily absolute gains were different, $2\frac{1}{2}$ lbs in cattle and $\frac{1}{3}$ lb in sheep, but both required 1040 lbs feed to gain 100 lbs weight. Moreover, it appears that rabbits and cattle are equally efficient converters of feed into live weight³⁴, presumably at equivalent physiologic ages.

Kleiber's observation that the ratio of maximum food consumption to basal metabolism, and also that the total productive efficiency, is independent of species and live weight cannot be generally true. An extreme deviation from this rule is the relatively very low ratio of food consumption to basal metabolism in children, as contrasted to that in growing farm animals. Another illustration is that pigs grow at a higher energetic efficiency than cattle because, presumably, pigs have a relatively greater feed-consumption capacity in proportion to maintenance cost than cattle. Lactating dairy cattle, of course, consume a great deal more feed in comparison to their maintenance cost than do beef cattle. Then, too, Kleiber's rule cannot hold for animals differing in physiologic age. Indeed, as noted in Chapter 1, whatever dif-

³⁰ Lusk, G., "The Science of Nutrition," Saunders, p. 569, 1928.

³¹ Kleiber, M., *Tierernährung*, 5 (1933); also in Report on the Conference on Energy Metabolism, National Research Council, Committee on Animal Nutrition, Washington, 1935.

ferences there are in efficiency of different species and individuals at different ages must be due to differences in the ratio of feed consumption to maintenance cost.

Generalizations of the type of Rubner's and Kleiber's necessarily involve large margins of error. None the less they are useful, serving as pegs on which to anchor ideas, however insecurely.

The difference between Rubner's and Lusk's estimates of 35 per cent and 20 per cent efficiency, respectively, for early postnatal growth (during the first doubling of body weight) of pigs, and Tangl's values of 62 per cent efficiency for prenatal growth of chicks does not imply a contradiction. It is entirely possible that the additional muscular, thermo-regulatory, digestive, excretory, and related activities characterizing postnatal life may involve a sufficient energy increment to account for this difference in gross efficiency.

Moreover, the increase in size of a given animal associated with increasing age would be expected to increase the energy cost of its maintenance and reduce correspondingly the total efficiency of growth unless this increase in maintenance is compensated by an increase in growth rate. In the case of different species, such as in cattle and chickens, there is such compensation and, therefore, nearly the same efficiency of growth, at *equivalent physiologic ages*. This is substantiated by the efficiency data cited on pp. 51-3.

But the increase in size associated with increasing age in the same animal is not thus compensated by increase in growth rate, with resulting decrease in efficiency of growth with increasing age or weight.

An interesting aspect of Rubner's generalization is that he excludes man therefrom. The human infant retains during the first doubling of body weight about 5 per cent of the dietary energy while the other species retain, according to Rubner, 35 per cent of the dietary energy. The reason for this exception will become clear on examination of the age curves of growth in man and other species in Chapter 16. In comparison to the body weight, the growth rate of the human infant is very much less than that of any other species; in other words, the maintenance cost of the human infant is greater in comparison to his rate of gain than is that of other species³⁵.

Let us next cite a few illustrations on the efficiency of growth of farm animals, and the most common laboratory animal, the rat. As previously noted, postnatal data are not well defined because of the differences in the availabilities of the various diets and differences in the energy equivalents of the weight gains (Ch. 2, 5). The following data³⁶ illustrate the variability in the energy content of the weight gains of "paired" rats, that is, rats apparently alike in every respect including nature and quantities of food consumed.

³⁵ Cf. Lusk, G., "The Science of Nutrition," pp. 568-571, 1928.

³⁶ From Mitchell, H. H., and Carman, G. G., *Am. J. Physiol.*, **76**, 406 (1926).

Final weight (g)	Sex	Days on experiment	Gain in weight (g)	Combustion value of the gains (Cal/g)
118	M	56	25	0.32
134	F	56	38	2.66
165	M	56	68	2.44
169	M	56	73	2.56
228	F	156	162	2.35
241	M	156	180	2.84
185	F	156	119	3.26
223	M	156	157	3.10
280	M	156	215	2.37

Both the gains on a given food intake and the caloric values of the gains vary enormously in these homogeneous and pair-fed animals. The variability is likely to be far greater when comparing heterogeneous animals.

Fig. 3.1—The influence of the rate of growth (brought about by varying the litter size in suckling rats) on the heat production for *given weights*. The rapidly growing rats exhibited a higher heat production regardless of the reference base employed, than did the normals. Courtesy E. B. Brody and *Am. J. Physiology*, 138, 180 (1942).

The following efficiency estimates, randomly listed from data by the same authors, illustrate the order of efficiency of growth of rats and its variability.

Initial weight (g)	Weight gain (g)	Metabolizable energy consumed (Cal)	Energy in the gains (Cal)	Gross efficiency of growth with respect to consumed metabolizable energy (%)
84	34	1302	8	0.6
89	76	1852	156	8.4
70	122	4642	352	7.6
70	194	5210	593	11.4
70	220	5539	751	13.6

Rubner's rule of 35 per cent efficiency does not apply to these rats, since these animals are beyond the age of first doubling of body weight.

The following estimates³⁷ on the gross efficiency of growth of Jersey cattle with respect to *TDN* consumed indicate an early efficiency near 35 per cent with a decline to 5 per cent at age 2 years.

Age (mos)	Live weight (lbs)	(1) Gains (lbs/day)	(2) Gains (Cal/day) (1) x 909	(3) <i>TDN</i> consumed (lbs/day)	(4) <i>TDN</i> (Cal) (3) x 1814	Gross efficiency (%) (2)/(4)

The conversion factors employed, 1 lb TDN is equivalent to 1814 Cal (or 1 g TDN to 4 Cal), and 1 lb gain in live weight is equivalent to 909 Cal (or 1 g to 2 Cal), may be justly criticized, as the caloric equivalents per unit weight undoubtedly change with age and with other conditions. Thus, the combustion value per gram fat is equivalent to that of 2 g protein. In addition, 2 g protein is associated with about 6 g of water, while fat is not. An animal gaining protein alone would, therefore, gain 8 times as much weight, yet the same amount of energy as one gaining fat alone. This is an extreme illustration. It was reported³⁸ that rats fed a relatively high protein diet had an average combustion value of 1.8 Cal per g of tissue, whereas rats fed a low-protein diet had an average combustion value of 2.8 Cal per g (highest value was 3.6 Cal/g). The combustion value varies even for the dry tissue from 5.6 to 5.8 Cal per g. There are also variations in the energetic availability of TDN depending on many conditions. The tables, however, indicate the general trend.

The following estimates on steers indicate the nature of the energetic efficiency of beef production and how it is related to weight. As before, TDN is assumed to be equivalent to 1814 Cal per lb and 1 lb gain in weight to 909 Cal per lb.

Initial weight (lbs)	Weight gain (lbs)	TDN consumed (lbs)	Gross efficiency (%) (gain, Cal/TDM, Cal)
764	388	3400	5.7
412	488	2691	9.1
485	402	2195	9.3

The efficiency of beef production within the given limits is thus seen to be below 10 per cent. The apparent efficiency would be reduced still further by deducting the unedible part of the body weight.³⁹

³⁸ Johnson, S. R., Hogan, A. G., and Ashworth, U. S., Univ. Missouri Agr. Exp. Sta. Res. Bull. 246, 1936.

³⁹ Leitch, I., and Godden, W., (Imperial Bureau of Animal Nutrition, Tech. Communication 14, 1941) estimate that for fattening in beef animals, 9 to 10.7 cwt live-weight, the gross efficiency is 5.7 per cent with respect to dry matter; 16 per cent with respect to energy; 9 to 12 per cent with respect to protein.

The fact that efficiency is independent of body weight as such, but that it is rather related to physiologic age, is indicated by the following efficiency estimates on two groups of S.C. White Leghorn Chickens, one group growing very rapidly and the other growing slowly. The estimate of the fast-growing groups was based on unpublished data by Gustav Heuser; that of the slow-growing group on data by Card and Kirkpatrick (Storrs Station, Bull. 96). In spite of size differences the early-growth efficiency of chickens is very near that of cattle. Efficiency values of the same order were obtained for early growth of rats.

Age	Body weight (g)		% efficiency	
	Heuser	Card and Kirkpatrick	Heuser	Card and Kirkpatrick
1 day	39.9	37		
1 week	62.7	53	35	26
2	121.4	83	38	22
3	193	119	33	19
4	380	173	32	21
5	481	229	29	18
6	504	315	23	20
7	719	410	18	19
8	759	495	26	15
13		878		8.0
24		1490		2.5

It was assumed in the above computations for chickens that the metabolizable energy equivalent of the feed (not *TDN*) was 3 Cal/g, and 1 g weight gain is equivalent to 2 Cal. The results would, of course, differ with the conversion factors employed. (Heuser's ration was: yellow corn 57, wheat middlings 20, egg white 10, dried liver 7.5, cod liver oil 1, steamed bone meal 2, lime stone 1, salt 0.5.)

As previously noted, there is an enormous amount of data on growth and feed consumption, published and unpublished, in our agricultural experiment stations from which total efficiencies may be estimated, but which cannot be analyzed here.

3.3: Energetic efficiency of milk and egg production. The problem of energetic efficiency of milk and egg production will be discussed in detail in Chapters 21 to 23. This section compares, for the sake of completeness, the gross efficiency of milk and egg production with that of growth. The gross energetic efficiency of milk production in "good" dairy cattle and dairy goats is of the order of 33 per cent with respect to *TDN* consumed (assuming 1 lb *TDN* = 1814 Cal); and this efficiency, like that of growth at a given *physiologic age*, is roughly independent of body weight, or even of species as such. When other conditions are equal, it is approximately the same in dairy cattle, dairy goats, and white rats, as indicated in the table on p. 857. It is true that the milk production *per unit body weight* is greater in small than large animals, but the basal metabolism, or maintenance cost, *per unit body weight* is also greater in small than large animals with the net result that the two balance and the energetic efficiency is approximately independent of body weight. In this case Kleiber's rule holds. About $\frac{1}{3}$

of the consumed *TDN* (1b *TDN* \times 1814) is usually recovered in the milk of good dairy animals regardless of body size—if other conditions are equal.

The total energetic efficiency of milk production is comparable in magnitude to the total efficiency of very early postnatal growth, but it is very much greater than of beef production at later ages.

As egg is a more complex substance than milk, it requires more time for its elaboration, so that a greater proportion of the chicken's food would be expected to be used for maintenance in elaboration of egg than of an energetically equivalent quantity of milk with consequent lower total efficiency for egg than for milk production. The total energetic efficiency of egg production in good egg producers is approximately half that of milk production in good dairy animals.

It thus seems that, when other conditions are equal, the greater the structural complexity of the product the lower the energetic efficiency of its production. Milk, the least complex product, may be produced at the highest efficiency; this is followed by egg, and this by growth (meat).

3.4: Relation between the net energy category of feed and the efficiency of productive processes. The *net energy* of a feed is, by definition, the part transformed into the desired product: work, body tissue, milk, egg, and so on. The *net* efficiency of a productive process [eq. (1.2), excluding maintenance cost] should, therefore, be about 100 per cent with respect to the *net energy* category of feed ingested. The net efficiency of growth should be less if the efficiency is computed with respect to the *metabolizable-energy* category of feed (perhaps 70 per cent in cattle), and least (50 per cent in cattle) if it is with respect to the *gross-energy* category of ingested feed.

In discussing efficiency it is, therefore, imperative to specify what category of efficiency—gross or net—and what category of feed—gross, digestible, metabolizable, or net—is under consideration. The literature on productive processes is confusing, from the energetic-efficiency viewpoint, either because of poor specifications or because of lack of appropriate conversion factors under the given feeding conditions.

Thus, as explained in the preceding section, the *gross* efficiency [including maintenance cost, (eq. 1.1)] of milk production with respect to *TDN* consumption (assuming that 1 lb *TDN* is equivalent to 1814 Cal) is about 33 per cent. Yet Kellner's⁴⁰ balance experiments on three lactating cows yielded an efficiency of about 65 per cent.

Kellner, however, referred to the *net* efficiency [not including maintenance cost, eq. (1.2)], and the efficiency was with respect to the *metabolizable-energy* category of feed. It will be shown in Chapter 21 that the *net* efficiency of our data is of the same order as that of Kellner's.

⁴⁰ See Armsby, H. P., "The Nutrition of Farm Animals," p. 493, 1917; Kellner, O., 5th Int. Kong. Milchwirtschaft, 1911; Kellner, O., "Die Ernährung der landwirtschaftlichen Nutztier," Berlin, 1919. Armsby and Moulton, "The animal as a converter of matter and energy," New York, Reinhold Publishing Corp., 1925.

Jordan⁴¹ and Eckles⁴², like Kellner, reported their milk-secretion studies in terms of *percentage utilization* of the *metabolizable* category of feed *above the maintenance cost*, which in our terminology is the *net efficiency* [eq. (1.2)] of milk production with respect to pounds *TDN* consumption ($\text{lb} \times 1814$). Jordan's and Eckle's values were near those of Kellner's. Jordan reported 49, 57, and 64 per cent of "feed utilization"; Eckles reported 63, 68, 67, 51, 73, 60, 63 and 50 per cent utilization.

The *net efficiency* of milk production, not counting maintenance, is thus seen to be nearly double that of the *gross efficiency*, including maintenance. It is surprising that despite great differences in *gross efficiency* of growth, milk production, and egg production, the *net efficiency*, excluding maintenance [eq. (1.2)], appears to be roughly of the same order in all three processes, as will be shown presently for milk production (Ch. 21) and egg production (Ch. 23). Thus, Terroine and Wurmser⁴³, who worked over growth data by Kellner, Kohler, and Fingerling, concluded that the *net efficiency* of gains in weight ranged from 45 to 63 per cent in a cow and 52 to 84 per cent in a growing pig—values close to those for the *net efficiency* of milk and egg production.

The differences in the *gross efficiencies* of growth, milk production, and egg production may reflect differences in the time intervals required to produce unit energy in the form of milk, egg, and body gain, with corresponding differences in maintenance cost and consequently differences in gross efficiency. Time, and therefore maintenance, profoundly affect the gross efficiency of all productive processes.

Jordan⁴⁴ summarized the efficiencies of farm animals in terms of yield of edible solids per 100 pounds digestible organic matter consumed as follows:

Animal and product	Efficiency in terms of edible solids per 100 pounds of digestible organic matter in the ration
Cow, milk	18.0
Hog, carcass	15.6
Calf, carcass	8.1
Fowl, egg	5.1
Fowl, carcass	4.2
Steer, carcass	2.8
Sheep, carcass	2.6

This is probably a good practical representation of the *relative total efficiencies* of the several classes of animal converters as they existed in 1900. Biologically and energetically, however, the representation is vague. Thus, the caloric equivalence of "organic matter" obviously varies with its composition. Moreover, the amount of "edible solids" varies with the dietary

⁴¹ Jordan, W. H., N. Y. (Geneva) Agr. Exp. Sta. Bull. 197, p. 24, and 20th Report, p. 29. See also his book, "Feeding Farm Animals," New York, 1901.

habits of the consumer. Thus intestine (tripe) is a delicacy in some countries and offal in others, and biologically considered the energy equivalent of the offal is no less important than the edible parts.

This table underestimates the efficiency of modern dairy cattle, not only because the gross efficiency of milk production during the lactation period is nearer 33 per cent than 18 per cent, but also because beef animals yield only their bodies as edible end products for their rearing, whereas dairy animals not only eventually yield their bodies but also produce milk and calves. This, in effect, increases their life-time efficiency by spreading the cost of rearing over a much larger volume of edible product.

As previously noted, good dairy cattle, typified by experiment-station herds, produce milk at approximately 33 per cent gross efficiency with respect to *TDN* consumed—about $\frac{1}{3}$ of the *TDN* energy is recovered in the milk (assuming 1 lb *TDN* is equivalent to 1814 Cal). Egg is produced in comparatively good layers at approximately half this gross energetic efficiency, perhaps 16 per cent. The gross energetic efficiency of meat production declines rapidly with increasing age.

Pigs probably have a considerably higher gross energetic efficiency of growth⁴⁵ because they consume more concentrated feed in more available form—their “work of digestion” may be less—because they may have better appetites, consuming more nutritionally available feed above their maintenance level, or what is the same, they may have a relatively low maintenance level in comparison to their feed capacity. Pigs also have an exceptionally high dressing percentage in comparison to other animals as indicated by the following abbreviation from Whetham’s extensive tables⁴⁶, the average of “Large White,” “Middle White” and “Berkshire” breeds.

Live weight (lbs)	Carcass (%)	Approximate age (days)	Live weight (lbs)	Carcass (%)	Approximate age (days)
60	69	97	190	81	204
70	71	105	200	81	213
80	73	114	210	81	221
90	75	122	220	81	229
100	76	130	230	82	237
110	77	138	240	82	246
120	77	147	250	82	254
130	78	155	260	82	262
140	79	163	270	82	270
150	79	171	280	82	279
160	80	180	290	82	287
170	80	188	300	83	295
180	80	196			

While the dressing percentage is estimated to be about 75 per cent for average hogs, it is thought to be 56 per cent for calves (average live weight

⁴⁵ To produce 1000 Cal live weight, fattening pigs need 77 per cent as much S.E. (starch equivalents) as bullocks. K. Breirem, cited by I. Leitch and W. Godden, Imp. Bureau of Nutrition, Tech. Communication 14, 1941.

⁴⁶ Whetham, Elizabeth O., “Pigs Breeders’ Annual” (England), 1934–5.

190 lbs), 55 per cent for cattle (average live weight 940 lbs) and only 47 per cent for sheep and lambs (average live weight 85 lbs).

It is interesting to comment on the magnitude of the meat industry. The 1940 per capita meat consumption in the United States was about 150 pounds (67 lbs pork, 55 lbs beef, 7 lbs veal, 7 lbs lamb and mutton, 12 lbs lard). In spite of some 3 billion pounds more meat production in 1942, the war demands are expected to reduce the per capita civilian meat consumption to 135 pounds. The number of animals dressed in 1940 included about 78 million hogs, 15 million cattle, 10 million calves, and 22 million sheep and lambs. Dairy and poultry statistics will be cited, respectively in Chapters 21 and 23.

3.5: Summary. Agriculturally productive processes may be classified into work and growth processes, the latter including growth of tissue, fat, milk, egg, wool, and so on.

While the body is not a heat engine, the *theoretically maximal* efficiency of muscular work appears to be of the same order as of Carnot's heat engine, 40 to 50 per cent. The *actual gross maximal* [eq. (3.1)] efficiency of muscular work with respect to oxidized nutrients, which is roughly equivalent to the free energy, ΔF , of thermodynamics, is of the order of 25 per cent; that is, nearly $\frac{1}{4}$ of the nutrients oxidized in an animal working at top speed may be recovered in the form of useful mechanical work. The maximum *net* efficiency [eq. (3.2)], not including the standing maintenance cost, is about 28 per cent; the maximum *absolute* efficiency [eq. (3.3)], not including the energy expense when walking without a load, is about 35 per cent.

The growth process probably also involves work components, work of converting amorphous food materials, into organized tissue, but it is very difficult to estimate its magnitude partly because it is impossible to separate the energy expended for work from that for maintenance. The "maintenance" concept is also very complex, including many processes, some of which, as the catabolism of nutrients by enzymes excreted or liberated into the medium following the death of organisms, really have nothing to do with maintenance. Such unavoidable losses, of no benefit to the organism, may also occur in living organisms. Some of the maintenance energy represents real work—work of circulation, respiration, secretion, excretion, and so on; and some energy may be expended to "maintain" the thermodynamically unstable and "improbable" structural living configuration.

The gross efficiency of growth, including the maintenance complex, is 3 per cent for certain autotrophic bacteria, about 10 per cent for yeast, 60 per cent for prenatal growth, 35 per cent for early postnatal growth, 5 to 10 per cent for beef production in later ages, near 16 per cent for egg production, and about 33 per cent for milk production. The net efficiency, which does not include the maintenance item is, of course, higher by the maintenance cost, and is roughly the same for all these processes.

The gross energetic efficiency of growth depends on the physiologic age interval under consideration because the older the animal the greater the maintenance tax in comparison to the productive increment. Thus Hammond⁴⁷ reported that whereas 22½ lbs feed "weighed dry" is required to produce a pound of saleable beef for cattle finished at 3 years, it required only 11½ lbs feed to make a pound of saleable beef for cattle finished at 1½ years.

The efficiency of work, growth, milk production, egg production, and so on, is discussed historically and comparatively. Body size as such, when other conditions and especially *physiologic* age are equal, does not affect energetic efficiency, although it is an extremely important factor in the profit complex, which involves overhead expenses, such as the human labor of management, housing, and so on. The profit aspect—contrasted to the biologically energetic efficiency aspect—of body size, with special reference to milk production, is discussed in Chapter 22.

⁴⁷ Hammond, J., "The Farmers' Weekly" (British), p. 13, Aug. 16, 1935.

Chapter 4

Specific Dynamic Action and Efficiency of Productive Processes

The hypotheses which have been presented on specific dynamic action transcend one's power to coordinate them. *Graham Lusk*

4.1: Specific dynamic action, basal metabolism, and endogenous nitrogen excretion. As previously explained [eq. (2.10)], the *physiologic fuel value*, or the *metabolizable energy*, of a diet is composed of (1) net energy, or physiologically free energy, comparable to ΔF in thermodynamics, and (2) specific dynamic action¹ abbreviated to *SDA*, which is a tax to entropy, comparable to ΔS in thermodynamics, an extra heat increment incident to the nutritive process in total, including the energy cost of excretion of the end products.

One may say that the *resting* heat production of an animal in a thermoneutral environment is made up of two components: (1) *basal metabolism*, which is the irreducible energy cost of maintenance during complete rest, and (2) *SDA*, an energy waste incident to food utilization. *Basal metabolism* is, therefore, the resting energy metabolism in a thermoneutral environment in post-absorptive condition, uncomplicated by heat increments incident to food utilization or to low or high environmental temperatures.

*Basal metabolism*² is a convenient starting point for measuring the various heat increments, as heat increments of: fever, feeding, lactating, gestating, working, keeping warm in cold weather, and so on.

*Endogenous nitrogen*³ *excretion* is similarly a convenient starting point for measuring various nitrogen-excretion increments as, for example, those due to food ingestion, and it is defined, empirically, as the lowest level of nitrogen excretion attained after an empirically defined time interval on a low-nitrogen but otherwise complete diet.

Both the basal energy and endogenous nitrogen levels are useful base values for computing the energy and nitrogen costs of maintenance. The relation of these basal values to total maintenance and to body size will be discussed in detail in Chapters 13, 14, and 15; they are here considered in their relation to the *SDA* problem.

¹ Rubner, M., "Die Gesetze des Energieverbrauchs bei der Ernährung," Leipzig, 1902; also *Z. Biol.*, **42**, 261 (1901).

² Du Bois, E. F., "Basal Metabolism in Health and Disease," 1936.

³ Folin, O., "A theory of protein metabolism," *Am. J. Physiol.*, **13**, 117 (1905).

One method of measuring the *SDA* of protein or of amino acids is by the ratio of the heat increment above the basal level to the nitrogen excretion above the endogenous nitrogen level following a single meal, as illustrated in Fig. 4.3 and other methods are illustrated in Figs. 4.1 to 4.7.

Fig. 4.1—The heat increment of feeding in several classes of farm animals.

There is nothing particularly edifying about the term “specific dynamic action” outside of its historical connotation. Instead of the *SDA* designation, others are used, including calorigenic effect of food, heat increment of feeding, thermogenic effect, and thermal energy.

The calorigenic effect of drugs as of dinitrophenol⁴, or of hormones such as thyroxine or adrenaline, consists in raising the metabolic activities of the body

⁴ Cf. Brody, S., *Ann. Rev. Biochem.*, 3, 341-3 (1934).

cells. Voit⁵ suggested and Lusk⁶ advocated Voit's theory that the nutrient fragments likewise raise the metabolism of the body cells. This theory has, however, apparently been disproved by the observation⁷ that when the liver is removed, that is, when the deamination of protein is prevented (deamination of protein occurs mostly in the liver and to a less extent in the kidney⁸), nutrients exert no specific dynamic effect; Lusk⁹, therefore, bravely discarded his old teachings and adopted the thermodynamic viewpoint.

The fact that about 80 per cent of the resting *SDA* originates in the viscera¹⁰ substantiates the theory that the *SDA* is due to the protein catabolism as such rather than to stimulation of body cells.

The theory that *SDA* is the work of digestion¹¹ has been disproved by feeding bones and meat extract¹² and agar and cathartics¹³ when no *SDA* was observed. Moreover, injecting amino acids gives the same *SDA* as ingesting¹⁴.

It is instructive to reflect on the fact that, although the phenomenon of heat increment of feed was observed over a century and a half ago¹⁵, and although it has aroused enormous interest and elicited a great literature⁶, there is no generally accepted theory, nor indeed generally accepted quantitative definition of *SDA*.

This is Rubner's¹ definition of *SDA*: If the *postabsorptive* energy expense of maintenance of a mature normal animal (dog) at *thermal neutrality* is 100 Cal a day, then if the animal consumes 100 Cal in the form of meat, its heat production will increase to 131 Cal for the day. The extra 31 Cal is the *SDA* of the 100 Cal of meat. If the animal is given 131 Cal, its heat production will increase to 137 Cal, and so on, as shown in the following table.

Relation between energy in the food and heat production by the animal.

Trial No.	Protein Diet (Meat)		Fat Diet		Cane-sugar Diet	
	Food energy	Heat production	Food energy	Heat production	Food energy	Heat production
1	0	100	0	112.7	0	100
2	100	130.9	112.7	114.3	100	106
3	130.9	137.3	114.3	114.5	106	106.4
4	137.3	139.3	114.5	114.55	106.4	106.42
5	149.3	139.9				
6	139.9	140.1				
7	140.1	140.2				

It appears from the above table that under the given conditions the *SDA* of lean meat is 40 per cent of the intake energy; of fat, about 15 per cent; of

sucrose, about 6 per cent. That is, for example, of 115 Cal of physiologic fuel value (metabolizable energy) ingested in the form of fat, about 15 Cal is the entropy tax and 100 Cal is the physiologically free energy employed for maintenance or related useful purposes.

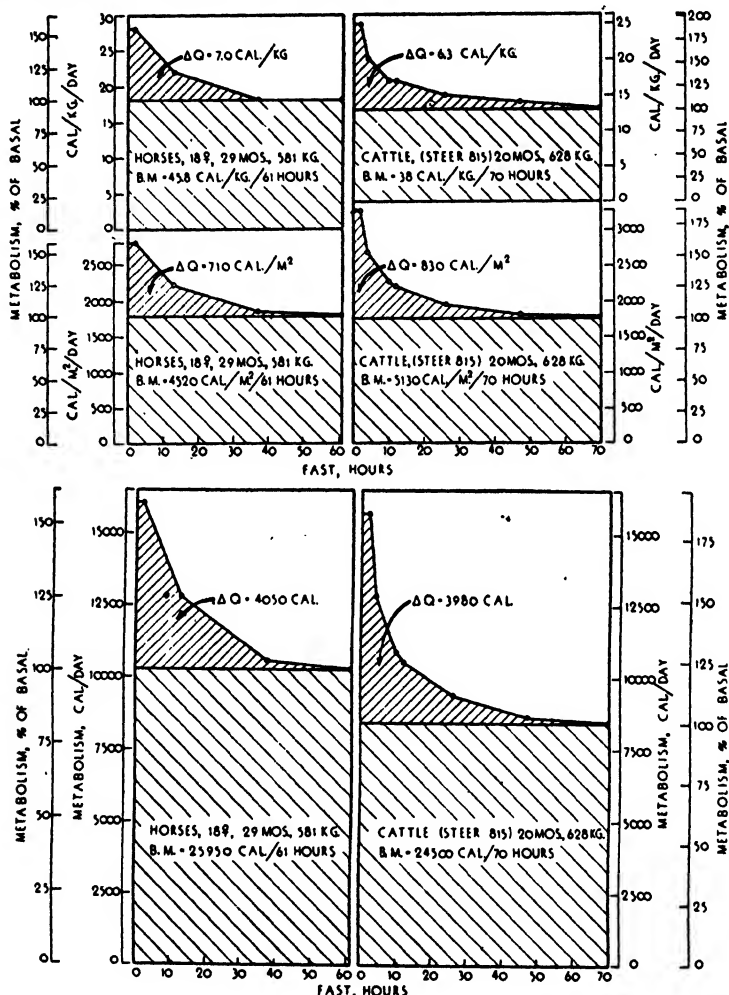

Fig. 4.2a—The heat increment of feeding in several classes of farm animals. The B.M. areas represent basal metabolism and the ΔQ areas the heat increment of feeding for the intervals shown on the time axis.

Murlin and Lusk¹⁸ substantiated Rubner's values: "If what we now call the basal *metabolism* of a typical animal be 100 Cal, per day, and 100 Cal be administered to the animal of each of the several foodstuffs on different days, then the heat production of the animal after receiving meat protein

¹⁸ Murlin, J. R., and Lusk, G., *J. Biol. Chem.*, **22**, 15 (1915). Murlin, *et al.*, *J. Nut.*, **12**, 613 (1936).

will rise to about 130 Cal, after glucose to about 106 Cal, and after fat to about 104 Cal. These are typical average results." The typical animal is presumably a mature one.

Fig. 4.2b—See legend of Fig. 4.2a.

Kriss, Forbes, and Miller¹⁷ reported that the average heat increment (in 100-g rats) resulting from the *addition to a maintenance ration* (see Sect. 4.2) of casein, starch, and olive oil, respectively, expressed as percentages of the metabolizable energy of these supplements, were 31.4 per cent for casein, 22.5 per cent for starch, and 16.5 per cent for olive oil. These values, with

¹⁷ Kriss, M., Forbes, E. B., and Miller, R. C., *J. Nut.*, 8, 509 (1934).

reference to maintenance metabolism as base, were greater than with reference to fasting metabolism as base.

The literature on *SDA* is large and, as Lusk remarked in the quotation at the head of this chapter, very confusing. Rubner's theory¹ seems to be general enough, or perhaps vague enough, to embrace all thermodynamic theories. It is that the *SDA* represents the waste heat from the many intermediate and side reactions and oxidations incident to the nutritive processes. One may compare it to the waste in lumber manufacture—the trunks are utilized for the building industry but the branches and sawdust go into the brush fire; or one may compare it to the energy waste in a heat engine, part of which is free energy convertible to work and the rest is wasted, swelling the tide of entropy.

The contradictions in the literature on the *SDA* values of a given nutrient are due to the fact that the magnitude of the *SDA* of a nutrient is not a constant but, on the contrary, is highly variable depending on many circumstances, such as on whether or not the nutrient is stored or otherwise usefully employed; and this in turn depends on the balance between nutrients, plane of nutrition, environmental temperature, muscular or other productive activity, age, and so on.

Moreover, every amino acid has a characteristic *SDA*, a characteristic speed of utilization and catabolism, which influence the real or apparent end result. Thus, the *SDA* of the oxidative deamination of alanine is much greater than of the hydrolytic deamination of arginine. The liberation of nitrogen from the imidoazol ring of histidine is no oxidation. The *SDA* also depends on the deaminized residue.

The *SDA* value, moreover, depends on the reference base and units employed, whether it is represented in terms of heat produced to total nitrogen excreted, to nitrogen excreted above the endogenous, or above the maintenance level; to grams of nitrogen, or to equivalents of nitrogen, and so on.

By way of illustration, let us discuss the fate of the amino acid alanine when it is not stored in the body either because of excess ingestion or because of unbalance of the amino acid mix. In such case the amino acid is deaminized, producing urea, which is excreted by the kidney, and sugar, either stored in the body, converted to fat, or oxidized. The deamination may occur by three different methods: (1) oxidative; (2) simple; (3) hydrolytic.

¹In the first of the three reactions oxygen is consumed and, consequently heat is produced, equivalent to 4 Cal per g N catabolized. In the formation

of urea from NH_3 , there is also heat production, about 4 Cal per g N involved^{18, 19}, responsible for perhaps 20 per cent of the *SDA* of protein²⁰.

Then, too, the urea and other end products are excreted by the kidneys at a considerable energy cost, perhaps 1 to 2 Cal per g N excreted, accounting perhaps for 25 per cent of the *SDA* of the catabolized protein, attributed to kidney work^{19, 21}. The efficiency of the kidney is estimated to be 2 to 5 per cent, 98 to 95 per cent of its energy expense being wasted as heat only, which heat is part of the *SDA* heat.

When the deaminized fragment is oxidized there may be, in the case of alanine, an additional heat production of about 30 Cal per g N excretion¹⁹.

The heat liberated in deamination cannot be utilized for productive purposes; indeed, the heat of *SDA* is of the same nature as that given off as end product of muscular work. This is, of course, well known, having been observed by Rubner²², Anderson and Lusk²³, Rapport²⁴, Meyer²⁵ and others. The *SDA* heat, like the heat of muscular work, can be useful only for keeping the animal warm in cold weather. Yet a working or otherwise productive animal on a given diet and level is likely to have a smaller *SDA* than a non-productive one, because the nutrients are utilized at a higher rate for the productive process, leaving that much less for *SDA*. And in cold weather, the *SDA* spares the body from oxidizing body fuel to keep warm, giving the appearance of a decreased *SDA*. This is generalized by Rubner's *compensation theory*: there is a reciprocity between heat production by *chemical body-temperature regulation* and the *SDA*. Rubner found that the feeding of 320 g of meat to a dog at 7°C did not increase his heat production; but feeding 320 g meat at an environmental temperature at 30°C increased his metabolism (above the post-absorptive level) by 50 per cent. The reason that there was no apparent *SDA* at 7°C is that at this low temperature the "basal metabo-

²¹ The oxygen consumption of the kidney is said to be very high, about 9 per cent of that of the whole body at rest. However, Dock (loc cit) reported "that at least 80 per cent of the *SDA* is due to increased energy liberated by the hepatic cells during protein ingestion," and that "the oxygen consumption of the kidney was the same in rats on high and low protein intake, although the total oxygen intake of the former was 35 per cent greater than of the controls on the low protein diet." Borsook and Winegarden [*Proc. Nat. Acad. Sci.*, **17**, 3, 13, 75 (1931)], and Lublin [*Z. klin. Med.*, **109**, 371 (1928)] found an increased heat production as result of urea ingestion; but Carpenter [*J. Nut.*, **15**, 499 (1938)] found no effect on heat production in humans following ingestion of 30 or 40 g urea; nor according to Carpenter, did the following find increased heat production as result of urea ingestion: Tangl, *Biochem. lism" was higher on account of heat regulation, so that the heat of *SDA* replaced the heat of chemical regulation.

Another methodologic factor contributing to the *apparent* variation in *SDA* of protein is due to the failure to continue metabolism measurements, of both energy and nitrogen, until after the nitrogen and heat production return to the starting base level (Fig. 4.3). There are great differences in the rates of catabolism of different amino acids, different diets, in different individuals, under different conditions, and it is no easy matter to obtain *physiologically equivalent* values for the nitrogen and energy involved in the given *SDA* processes.

According to recent reviews²⁶, to which the reader is referred for details, some transformations of amino acids, as of glutamic acid²⁷, to urea (and other waste products) and to glucose are exothermic; others are endothermic, therefore, not realizable spontaneously, and requiring the driving force of a coupled exothermic reaction, and the *SDA* represents the difference between the energy produced and that used in the endothermic reaction. There is considerable disagreement among the experts²⁸ on all matters relating to *SDA*.

Carbohydrates undergo intermediate or preparatory stages, for example, phosphorylation (Ch. 6), on their path to storage (glycogen deposition) or oxidation, which changes involve a heat loss, the *SDA*. So do fats. Moreover, the conversion of fat to glucose²⁸ involves an energy loss of about 21 per cent, although the difference between the efficiency of fat and glucose utilization for work is only 11 per cent. Furthermore, physical changes, such as solution, osmotic pressure²⁹, and so on, involve additional heat liberation. The *SDA* of carbohydrates and fats may thus likewise be explained thermodynamically. Previous to his 1931 review, Lusk⁹ attributed the *SDA* of carbohydrates exclusively to a plethora or mass-action effect. More recently the evidence, including that in Lusk's³⁰ laboratory, favors a thermodynamic interpretation. There is, in brief, no very good correlation³¹ of *SDA* to blood-sugar level or even to the R. Q.³²

Fig. 4.3—The relation between heat production and urinary-nitrogen excretion plotted from data by Williams, Riche and Lusk (1912). The data were obtained on a female bull-terrier dog weighing 13.5 kg after feeding 1200 grams of meat and kept in a calorimeter at 26° to 27°C. The dog received no food for 24 hours preceding this feeding. The upper left chart represents the course of the ratio of Calories above basal (ΔQ) during given hours to nitrogen (in grams) above basal during the corresponding hours. The average ratio for the entire 21-hour period under observation is 11.1; that is, the total heat above basal produced during the 21 hours to the total urinary nitrogen excreted above basal during the same period was 11.1 Calories per gram of urinary nitrogen. (Williams, Riche, and Lusk say that "for the whole period the average increase in metabolism for every 100 calories of extra 100 calories of protein oxidized is 45 calories," and, "the ingestion of meat containing 900 calories in protein caused an increase in metabolism of 270 calories during a period of 20 hours, or the ingestion of 100 calories caused an increase of 30 calories in heat production.")

The lower left chart represents the heat production and urinary-nitrogen excretion in parallel manner; in the lower right chart the heat production and the urinary nitrogen excretion above basal are represented as percentages of the respective basal levels. This chart shows that the Calories reach a maximum value long before the nitrogen attains a maximum. It also shows that while the heat production was increased two times, the nitrogen excretion increased nearly six times. Note that the curve is not symmetrical about the maximum; the maximum occurs during the fifth hour, while the basal level is not reached again perhaps for 24 hours or longer.

4.2: Plane of nutrition and SDA. It is obvious that the *SDA* per unit food, especially of protein, will vary with the amount of nutrient taken and with the condition of the animal. Thus milk in moderate amounts ingested

by a suckling animal³³ will have an inappreciable *SDA* because the nutrients, especially the proteins, are largely stored, and the stored nutrients as such have no *SDA*¹. Likewise, a breakfast small enough so that the *SDA* of the dietary nutrients merely cancels that of the body nutrients which would be mobilized if the small meal were not taken, exerts no appreciable extra *SDA*³⁴. Richardson and Mason³⁵ demonstrated that if only a maintenance ration is allowed, and that fed at two-hour intervals, the heat production will not rise appreciably above the basal level.

By the same logic, the *SDA* will depend on the reference base employed. Employing basal heat production and endogenous nitrogen as reference base (Rubner method) as most physiologists do (Fig. 4.1), the *SDA* will be less than if the maintenance heat production is taken as reference base, as some agriculturists do (Kellner method).

The Kellner method³⁶, as interpreted by Kriss³⁷, takes the maintenance metabolic level as reference base, and the *SDA* is evaluated not on the basis of one meal, as by Rubner's method (Fig. 3.1), but by feeding the animal for days first on the maintenance level, then for days on the maintenance-food plus the test-food. The difference in heat production between these two planes represents the *SDA* of the test-food. The results obtained by the two methods are different: the *SDA* of protein, fat, and carbohydrate is higher when using maintenance than when using fasting heat production as reference base³⁸. The lower *SDA* obtained by the use of the fasting heat production as reference base is, as previously explained, attributed to the sparing of body nutrients from oxidation when food is fed to fasting animals. This is indicated by the fact that correcting for this sparing effect (on the assumption that the *SDA* of body nutrients catabolized in fast is the same as the dietary nutrients fed) raises the apparent *SDA* at submaintenance to near that obtained by the use of maintenance heat production as reference base.

Kriss' results with amino acids are, therefore, different from those obtained by the other investigators. Thus, Lusk and co-workers reported that while phenylalanine, alanine, and glycine have high *SDA*, glutamic acid, aspartic acid, and asparagine give negative results. Lundsgaard, Terroine and Bonnet, and others, reported that the *SDA* per gram nitrogen administered or excreted

is virtually the same for all amino acids. Kriss, on the contrary, using maintenance as reference base, reported that the important calorigenic factor is *metabolizable energy*—not nitrogen consumed or excreted (as reported by Lundsgaard, Terroine and others), and not the nature of the amino acids consumed (as reported by Lusk and associates). Kriss' results apparently contradict those of the preceding investigators. However, the contradiction

Fig. 4.4—The course of heat production in relation to feeding in cows.

may not be real, because Kriss' results are not comparable to those of the other investigators unless corrected for the difference in reference base employed.

The following table indicates that when maintenance is used as reference base, the carbon and hydrogen part of the amino acids is the major controlling factor in the level of *SDA*. This table harmonizes with the theory that at or above maintenance, the *SDA* represents the energy liberation of the intermediate chemical reaction of all nutrients, regardless of their nature.

SDA, in Calories, employing the maintenance level as reference base on rats. (Kriss³⁷)

Food Category	Glutamic acid 2.1 g	Alanine 1.8 g	Glycine 2.4 g	Glycine 1.8 g	Tyrosine 1.3 g	Aspartic Acid 2.0 g	Asparagine 2.0 g	Coefficient Variation (%)
Per 100 Cal energy metabolized	68	60	62	55	49	42	52	15
Per 100 Cal amino acid metabolized	92	82	69	65	49	63	67	20
Per 100 Cal gross energy metabolized	55	40	40	37	29	33	34	22

Per g amino acid fed	2.0	1.7	1.2	1.2	1.7	1.0	1.0	29
Per g amino acid metabolized	2.8	2.9	1.4	1.4	2.7	1.4	1.5	37
Per milimol amino acid metabolized	0.4	0.3	0.1	0.1	0.5	0.2	0.2	60
Per g extra urinary nitrogen excreted	29	13	7	7	19	13	7	60
Per g nitrogen fed	22	11	7	6	22	9	6	61

Forbes³⁹ suggested that the reference base for *SDA* computations should be neither basal (fasting) nor maintenance metabolism, but fasting heat production less the heat increment of utilization of body tissue catabolized during fast.

Forbes suggests the use of maintenance as the most practicable reference base, because "above maintenance, heat increments are measured with the minimum of ambiguity, with the heat production of energy equilibrium as the base value". Below maintenance the heat increments "are of mixed or indefinite significance by their contamination with energy expense of utilization of body nutrients catabolized".

To the present reviewer, however, it appears that the heat increment of a food above the maintenance level would also be "of mixed or indefinite significance by their contamination with energy expense of utilization", because the extra food above maintenance would be used for different purposes depending on the nature of the productive process. In the adult, the extra food would be used for fattening; in the young for growth; in the lactating animal for milk production, and so on, each involving a different energy expense of utilization and/or organization with resulting mixed significance.

There does not seem to be a definite *SDA* except under sharply defined reproducible conditions. The contradictory results and theories in the literature are due to the lack of definition of the influencing conditions. In the nature of the case, the *SDA*—and, therefore, the net energy—of a diet must differ with each of the influencing factors.

4.3: Nutrient unbalance and *SDA*. The absence of a limiting component from the metabolizable nutrients results in dietary unbalance and tends to increase the *SDA*.

Such an unbalance may be illustrated by the absence of one of the ten odd limiting amino acids from the dietary protein. As a result of the unbalance, the animal will be unable to synthesize its characteristic tissues or other

³⁹ Forbes, E. B., Pennsylvania Agr. Exp. Sta. Bull. 415, 1941.

products from the remaining amino acids. As the other amino acids are not utilized for protein synthesis, they are deaminized with consequently associated *SDA* as previously explained.

But other limiting nutritional factors may have a similar effect. Thus Mitchell⁴⁰ reported that lack of common salt reduces the utilization by chicken

Figure 4.5—The course of heat production in relation to feeding in goats.

of the metabolizable energy of a corn ration. Several reports⁴¹ indicate similar declines in utilization of metabolizable energy when phosphate is the limiting factor. While the influence of such deficiencies on *SDA* remains to be worked out, it is reasonable to assume that the *SDA* is increased because, by definition, the metabolizable energy is composed of net energy (the part

⁴⁰ Mitchell, H. H., and Carman, G. G., *J. Biol. Chem.*, **68**, 165 (1926).

⁴¹ Riddell, W. H., Hughes, J. S., and Fitch, J. B., *Kans. Agr. Exp. Sta. Tech. Bull.* 36, 1934. Kleiber, M., Goss, H., and Guilbert, H. R., *J. Nut.*, **12**, 121 (1936).

utilized for maintenance and production) and *SDA* (the part that is wasted), and decreased metabolizable-energy utilization necessarily means increased *SDA*.

4.4: Agricultural implications. The foregoing discussion indicates, first, that while the literature on *SDA* represents things that happen, the happenings are highly variable, depending on so many uncontrolled and uncontrollable factors that the results can be taken only as suggestive guides rather than as quantitative relations. Secondly, the results were obtained on dogs and rats, and it is evident that it is not possible to evaluate the *SDA* of individual amino acids or any simple nutrient in large farm animals, especially in cattle, with their basic diet of voluminous roughage and the associated fabulous flora and fauna that converts even urea to protein, and which ferments the rumen material with much heat production not differentiable from *SDA*.

Benedict and Ritzman published data on heat increment of feeding in steers⁴² and sheep.⁴³ These increments appeared unexpectedly early and large. The theory given was that the anaerobic fermentation in the rumen results in early formation and absorption of short-chain fatty acids, such as butyric, which exert a heat-simulating effect of the Voit variety, prior to the protein effect.⁴³ The author has accumulated a great mass of similar data, some illustrations of which are shown in Figs. 4.1 to 4.7, on which he hopes to report in detail in the future.⁴⁴ More controlled data on steers will be discussed in the following chapter.

Whatever the theories, which are necessarily more or less works of imagination, the fact is that the heat increment of feeding in large farm animals, especially in ruminants, fed dietary unbalanced roughage, is huge. This heat increment could be reduced or perhaps abolished by feeding at appropriate intervals a perfectly balanced diet, as did Richardson and Mason.³⁵ But, of course, farm animals are not kept for maintenance but for production, and they are never fed proteins of 100 per cent biological value in particular or perfectly balanced rations with regard to needs in general. It would not be very profitable to feed milk to dairy cows or eggs to laying chickens. Moreover, the handling of bulky farm feeds, especially by ruminants, involves other energy expenses than those investigated by Rubner, Lusk, Terroine and others on dogs, rats, and frogs. The heat increment of feeding in farm animals is therefore large, about 20 per cent of the gross energy of the good customary "balanced" mixed rations consumed (much higher when fed poor roughage alone), or a heat production in dairy cattle under "normal" feed conditions of about 50 per cent above that in the fasting condition.

Fig. 4.6—The course of heat production in relation to feeding in a series of cows and goats.

The large heat increment is an effective protection against cold; this explains, in part, the ease of wintering livestock, especially ruminants, on a poor hay diet in the cold western states where the temperature is often -40°F . (Ch. 11). By the same token, the *SDA* is a serious burden in hot weather,

Fig. 4.7—The course of heat production in relation to feeding in goats.

popularly expressed by saying that heavy feeding, especially with protein-rich feeds, "burns out" the animal, and one of the major problems of animal husbandry is to keep down the summer body temperature in productive animals (Ch. 11) and, thus, maintain productivity.

4.5: Summary. The basal energy and nitrogen (endogenous) catabolism

represent the irreducible caloric and nitrogen maintenance expenses respectively. Specific dynamic action, or *SDA*, or heat increment of feeding, or calorogenic effect of foods, represents the extra heat incident to the utilization of food or feed. The *SDA* of the extra protein is thus represented by the ratio of the resting heat production in a thermoneutral environment above the basal level to the nitrogen excretion above the endogenous level; or when using maintenance as reference base, it is represented by the ratio of the resting heat production above the maintenance level to the nitrogen excretion above the maintenance level. Similar representation may be made with respect to feed consumed or metabolizable energy consumed.

The *SDA* is very variable depending on the base level employed, on the plane of nutrition, on the balance between nutrients, on the nature of the productive process, and so on.

In cattle and sheep the *SDA* is further complicated by fermentation in the rumen, including heat generation in the rumen, a heat not differentiable from *SDA* heat. As a result, it is difficult to apply the great analytic literature on *SDA* from the thermodynamic viewpoint to the interpretation of the heat increment of feeding in farm animals, which must for the present rest on an empirical basis.

An analysis of the literature on dog and rat is, however, presented by way of background, giving special attention to the *SDA* following protein ingestion. If the ingested protein is not stored by the animal, its nitrogen is eliminated in the urine, and the carbon may be either stored in the body or oxidized. If all the carbon is oxidized, then, of course, since the physiological fuel value of protein is approximately 4 Cal/g, the heat increment of feeding of protein is about 4 Cal per g protein ingested, or $4 \times 6.25 = 25$ Cal per g of extra urinary nitrogen excreted. The usually observed *SDA* of protein (as of meat fed to a dog as shown in Fig. 4.1) is about 30 per cent of its metabolizable energy, from 8 to 12 Cal per g N excreted. The calorogenic effect of protein evidently varies with the nature and balance of the amino acids, and with the ability of the animal to store the protein or/and its deaminized fraction. Variations due to storage of protein may be eliminated by comparing calorogenic effects of a protein, not with the protein ingested, but with the extra nitrogen excreted. The extra heat will then represent the heat evolved in consequence of deamination, urea formation, and work of excretion of the nitrogenous waste products.

Attention is called to a few applications, such as the importance of the heat increment of feeding in outdoor wintering of animals in cold weather, or overheating in hot weather; the reduction of the *SDA* by frequent feedings of small meals, by muscular work, by balancing the nutrients in the ration, and so on.

The following chapter discusses the quantitative aspects of the influence of the plane of nutrition on the utilization of rations, with special reference to the heat increment of feeding in farm animals.

Chapter 5

Plane of Nutrition, the Principle of Diminishing Increments, and Efficiency

The law of diminishing returns has been applied to phenomena which involve decrease in the per unit effect of some causal factor as the magnitude of the acting factor increases. *W. J. Spillman*

5.1: The principle of diminishing increments. If the dietary metabolizable energy is perfectly balanced with regard to all nutritional needs, and if it is fed below the maintenance level, it merely replaces what the liver would have delivered to the blood for maintenance, and the *SDA* (the extra heat increment incident to food utilization process in total) will be inappreciable; the *SDA* of the diet merely replaces that of the body nutrients, which would otherwise have been mobilized for maintenance needs. Above the maintenance level, however, the *SDA* progressively increases, or the net energy (the total food energy, less *SDA* and other food-utilization energy expenses) decreases for successive increments of food intake. The tendency for decline in utilization of successive dietary increments is an example of a ubiquitous phenomenon often generalized by the principle of diminishing returns, or diminishing increments, or the Weber-Fechner law, or the law of mass action (Wilhelmy, 1850).

This principle has been long recognized: "Increase in yield cannot be proportional to the fertilizer supplied, but it rises at a far smaller rate" (Justus von Liebig, 1860). "The man blessed with plenty of this world's goods requires a correspondingly larger increase in his good fortune than does the poor man in order to derive the same amount of pleasure". "The more additional means are expended, the less striking is the effect, which stretches out to almost vanishing fineness" (F. A. Lange, 1870), and so on.

Liebig¹ was probably the first to formulate this idea under the name of the "law of the minimum", which may be shown to be a special case of, if not identical with, the principle of diminishing returns. Liebig's formulation is based on the relation of fertilizer supply to plant growth, as was, much

¹ Liebig, J. V., "Die Grundsätze der Agriculturchemie", 1855; "Die Chemie in ihrer Anwendung auf Agrikultur", 1876.

later, Mitscherlich's² and, independently, Spillman's.³ It is evident that additions of successive units of fertilizer cannot increase the yield proportionally, unit yield for unit fertilizer; otherwise the yield could become infinitely great by infinitely large additions of fertilizer. Likewise, the consumption of successive food portions cannot benefit the consumer by equal amounts.

A different biologic illustration of the principle of diminishing increments, discussed in detail in Chapter 16⁴, is the decline in the time rate of growth in weight gains, dW/dt , with increasing age following the pubertal inflection. This may be represented by several equations, such as

$$\frac{dW}{dt} = ce^{-kt} \quad (5.1)$$

in which k represents the *relative* rate (or when multiplied by 100, the *percentage* rate) of decline of the differential time gains in weight, and e is the base of natural logarithms.

Here is an actual numerical illustration⁵ of equation (5.1): The weight gains in successive months of a group of guinea pigs were observed to be 112, 90, 70, 56, 43, 35, 27, 21 ... grams. The value of k is then approximately: $\frac{112 - 90}{112} = \frac{90 - 70}{90} = \frac{70 - 56}{70} = \frac{56 - 43}{56} = .22$, or 22 per cent per month; $k = .22$ (approximately). Having the value of k , the value of c is easily computed.^{5a}

The *absolute* gains per unit time decline for successive months, but the *percentage* decline, $100k$, is constant. Since the gains in weight decline, the sign of k is negative.

Equation (5.1) may be written in several other forms, such as:

$$\frac{dW}{dt} = -k(A - W) \quad (5.2)$$

in which A is the mature weight, W , of the animal. The equation says in effect that the time rate of growth, dW/dt , is proportional to the remaining gains, $A - W$, yet to be made to reach the maximum weight, A . The farther from the mature weight, A , the more rapid the growth. As the animal gets older, the values of the gains remaining to be made, $A - W$, become progressively smaller, and so dW/dt becomes correspondingly smaller. The meaning of the numerical value of k is the same as in eq. (5.1).

^{5a} Becker, G. B., Smithsonian Mathematical tables, # 1871, Smithsonian Institution, Washington, 1924 (pp. 226 and 263).

The *differential* (time rate) equations (5.1) and (5.2) may be written in the *integral* (cumulative) form, giving not the differential weight gains, dW/dt , but the total body weights, W , as a function of age, t ,

$$W = A - Be^{-kt} \quad (5.3a)$$

In some cases, or from some viewpoints, A equals B (that is, $W = 0$ when $t = 0$), in which case the equation is

$$W = A(1 - e^{-kt}) \quad (5.4a)$$

Equations (5.1) to (5.4) are growth equations; but such growth (following puberty) is evidently an illustration of the principle of diminishing increments: the weight, W , gets larger with increasing age, t , but the increases per unit time become progressively smaller. Time, t , may be formally considered as the "causative agent", which has less and less effect on increasing the body weight. The physiologic significance of a physical time⁶ unit declines with increasing age (Ch. 19).

Instead of body weight, W , and age, t , we may relate milk-energy production, FCM (which represents milk corrected to 4 per cent fat, having a combustion value of 340 Cal per pound, or 750 Cal per kg), to TDN (digestible nutrient) consumption. In this case equation (5.3) becomes

$$FCM = A - Be^{-k(TDN)} \quad (5.3b)$$

The FCM yield rises with increasing TDN production, but at decreasing increments; the successive TDN units consumed elicit progressively smaller milk (FCM) production increments.

Instead of discussing particular products, as milk, or egg, or fat, or work, we may say that as the dietary gross energy, Q_g , consumption is increased by equal units, the net energy, Q_n , that is, the magnitude of the energy recovered in the given product, become progressively smaller; that is

$$Q_n = A - Be^{-K(Q_g)} \quad (5.3c)$$

In addition to its application to the effect of fertilizer increments on crop-growth increments, previously cited, this principle has been used in agriculture for relating the effect of feed-intake on its net energy value⁷, on growth rate^{8, 9}, and on milk production.⁹

Spillman⁸ and Jensen⁹ employed the equation

$$W = A - BR^n \quad (5.3d)$$

or when $A = B$,

$$W = A(1 - R^n) \quad (5.4b)$$

which are evidently similar to our equations (5.3a) and (5.4a), respectively, by letting

$$e^{-k} = R^n$$

R^n , or e^{-k} being the ratio of the successive increments—of the second to the first, third to the second, and so on, which is constant—resulting from the corresponding unit increments of fertilizer, food, or other causative factors. W is the cumulative weight associated with the consumption of n units of food.

5.2: The principle of diminishing increments and the net energy values of cattle and rabbit feeds. The net energy per unit food is the gross energy less the energy losses associated with its utilization (Sect. 2.3). From the law of the minimum, food-value tables notwithstanding, the net energy per unit food is not a constant but varies with many circumstances, such as the balance between nutrients *in relation* to their use in the body, amount of roughage, environmental temperature, endocrine constitution of the animal, and plane of nutrition. Brody and Procter⁷ have investigated mathematically, from the viewpoint of the principle of the diminishing increments, the influence of the plane of nutrition, or amount of feed ingestion, on the digestible-, metabolizable- and net-energy values of steer and rabbit rations.

The data were obtained by Forbes *et al.*¹⁰ (Pa.) on 433-kg steers, Mitchell *et al.*¹¹ (Ill.) on a 613-kg steer, and Wiegner¹² on a 2.8-kg rabbit. The data (interpolated from smoothed curves) are given in Table 5.1 and the fit of equation (5.4) to the relation between net energy to total feed intake is given in Fig. 5.1.

As indicated by the statistical constants, Sy , r , and average deviations, equation (5.4) fits the data excellently.

The average equation for the Pa. (Forbes) steers is

$$Q_n = 24000(1 - e^{-0.00025Q_g})$$

which means that the average theoretical maximum net energy obtainable per day is 24000 Cal, and that the net energy, Q_n , rises with the intake of gross energy, Q_g , at decreasing increments; that for every 1000 Cal (about $\frac{1}{2}$ lb feed) increase in gross energy, Q_g , the decline in the net energy rise is about 2.5 per cent.

Fig. 5.3—The several losses (urine, methane, SDA., and feces) expressed as percentages of gross energy intake; also the net, metabolizable, and digestible energies expressed in terms of percentages of gross-energy intake; also, total heat production in terms of percentage of gross energy intake. The planes of nutrition (upper axis) are represented in the case of Forbes' steers in terms of gross energy at maintenance; in the case of Mitchell's steers they are expressed in terms of gross energy at "full feed".

Fig. 5.4—Coefficients of digestibility (upper half) and percentages of gross energy intake as digestible energy, digestible energy less methane energy, metabolizable energy, and net energy (lower half), plotted as functions of dietary gross energy and dry matter in steers and rabbits. The planes of nutrition (upper axis) are represented, in the case of Forbes' steers, in terms of gross energy at maintenance; in the case of Mitchell's steer, in terms of gross energy at "full feed".

feed, and for Mitchell's from about 65 to about 42 per cent. The declines in digestibility and metabolizability with increasing plane of nutrition are less conspicuous.

The other charts and tables call for less explanation. The upper segment in Fig. 5.4 presents the course of digestibility of the several dietary constituents with increasing plane of nutrition; the lower segment, the course of the percentage changes of the various energy categories with increasing plane of nutrition.

Fig. 5.5 presents the ratios of net energy to digestible energy plotted against plane of (1) gross energy intake, (2) digestible energy, and (3) basal energy.

Fig. 5.5—Ratios of net energy to digestible energy of the steer and rabbit data plotted against planes of net nutrition expressed in terms of 1, 2, etc., times gross energy intake (1G, 2G, etc.); digestible energy (1D, 2D, etc.), and "basal" energy (1B, 2B, etc.) intake with the corresponding equations. The data are plotted on arithlog paper. Note that the rabbit and steer data nearly coincide.

The equation of the ratio of net energy, Q_n , to digestible energy, Q_d , plotted against the plane of nutrition, Q_p , is

$$Q_n/Q_d = 43e^{-Q_p} + 54$$

indicating that the net energy does not fall below 54 per cent of the digestible energy.

Finally, Fig. 5.6 represents the influence of the plane of nutrition on (1) various energy losses; (2) various feed-energy categories; (3) body loss or storage for the three groups of animals. The gains or losses at any point of food ingestion are shown by the lengths of the ordinates at the given point between the indicated limits. Note that at the maintenance-balance level, the net energy value is identical with the basal-metabolism value, and the total heat production curve crosses the metabolizable-energy curve.

In summary, increasing food intake tends to reduce the net-energy value per unit food in accordance with the principle of diminishing returns. A detailed analysis is presented on the applicability of the principle to the

course of net-energy change of cattle and rabbit feeds with increasing plane of nutrition as observed on 430-kg and 615-kg steers and on a 2.8-kg rabbit.

5.3: The principle of diminishing increments and food consumption during growth. We have seen (Sect. 3.2.3) that as the animal grows larger, its main-

Fig. 5.6a—The relations between the plane of nutrition and the energy losses in the forms of feces, methane, urine, SDA in cattle; also energy storage (fattening) following the maintenance level, and body losses preceding the maintenance level. The gains or losses at any point of food ingestion are determined by the lengths of the ordinates at the given point between the indicated limits. At the maintenance level the net-energy curve crosses the “basal” metabolism curve, and the metabolizable-energy curve crosses the total heat production (basal plus SDA energy) curve.

tenance cost in comparison to weight gain increases and, therefore, the energetic efficiency of growth decreases; that is, as the animal approaches mature weight, the successive increments in body weight decrease per unit food intake; finally, growth virtually ceases while food consumption continues for maintenance alone.

Spillman³ and more recently Jull, Titus, and Hendricks⁸ applied the exponential, or diminishing-increment, equation relating growth to feed consumption in farm animals. Equation (5.4) represents very satisfactorily

Fig. 5.6b—Same legend as 5.6a.

the interrelation between weight and feed consumption *during growth*. It is evident that while the general principle is the same, the causative factors are of different nature for the effect of food-intake level on growth when age and

body weight are increasing than for the effect of food-intake level on the net energy at a constant age discussed in the preceding section.

Fig. 5.6c—A continuation of Fig. 5.6a, as it relates to the rabbit.

Fig. 5.7 is offered as an illustration of the relation of body weight to the total feed consumption with increasing age in immature chickens. The given equation indicates that the differential successive weight gains per kilogram feed consumed decline at the rate of 9 per cent; that is, each weight-gain increment per kilo feed consumed is roughly 9 per cent less than the preceding increment;

or what is the same, each increment is roughly 91 per cent of the preceding increment. The value 3.7 represents the theoretical maximal body weight in kg attainable by these chickens.

Fig. 5.6d—A continuation of Fig. 5.6a, as it relates to the rabbit.

For additional illustrations of the application of equations (5.3) and (5.4) to the interrelations between growth and feed consumption, the reader is referred to the literature cited and to the preceding chapter (Sect. 3.2.3) which contains data suitable for analysis from this viewpoint.

The foregoing discussion was concerned with the interrelations between

weight gains and "normal" food consumption associated with *advancing age* during growth, regardless of the efficiency or economy aspect. We also have the problem of influence of rate of weight gains and of plane of nutrition on feed economy (in contrast to *total* economy including cost of labor, etc.). Is it more economical to feed, for example, growing pigs *ad libitum* or to restrict to lower levels? It is usually assumed that the greater the feed consumption the more rapid the growth and the more economical the gains because of the saving of some maintenance cost per unit weight gain. On the other

Fig. 5.7—The relation between live weight and cumulative feed consumption in growing chickens.

hand, as previously noted, the greater the feed intake the lower the feed utilization, and the less the net energy per unit feed consumption. Moreover, underfed animals develop a "growth debt" which may enable them to utilize food more efficiently than well-fed animals.

Considerable research has been conducted at the Missouri Station¹³ on the growth of cattle on various planes of nutrition (Ch. 16). At this time reference is confined to the results of Ellis and Zeller¹⁴ on the feed required to in-

¹³ Missouri Agric. Exp. Sta. Res. Bulls. 43, 54, 55, and others.

¹⁴ Ellis, N. R., and Zeller, J. H., U.S.D. Agriculture, Tech. Bull. 413, 1934.

crease the body weights of pigs by 50 pounds, from an initial 70 to a final 120-pound level, when the pigs are fed *ad libitum*, at 4, 3, and 2 pounds feed per 100 pounds body weight. It was observed that while the growth rate decreased with decreasing feed allowance, the weight gain per unit feed consumed increased: one pound feed yielded 0.24, 0.29, and 0.32 pound of body weight gain when the animals were fed, respectively, 4, 3, and 2 pounds feed per 100 pounds live weight. The lowest plane of nutrition required 40 per cent more time to make a given gain in weight, yet yielded 33 per cent more body weight per unit feed. These differences in weight gains are, however, not indices of differences in gross *energetic* growth efficiency because the gains in the slowly growing animals contained more lean and water and less fat tissue than in the rapidly growing: the body fat constituted 36, 34, and 29 per cent respectively on the 4-, 3-, and 2-pound planes of nutrition.

5.4: The principle of diminishing increments and milk production. We shall discuss two types of diminishing increments in milk production: (1) that of energetic efficiency with increasing milk production level associated with inherent differences in lactational capacity on a standard ration, and (2) milk yield with increasing feed consumption in the same animals in which feed consumption is deliberately controlled by adding more or less of grain to the ration.

The diminishing-increment course of gross energetic efficiency of milk production with increasing milk yield is indicated in Figure 1.2 (page 5). The causal factor actuating the decline in increments is evident. The *gross* energetic efficiency, which carries the maintenance burden, can never be as great as the *net* efficiency, which is not thus burdened with the maintenance tax. With increasing milk yield the gross efficiency approaches the net efficiency as a limit. From its asymptotic nature, this approach occurs at ever-decreasing increments.

The causal mechanism actuating the decline in milk increments with successive units of grain intake in the same animal is of a more complex nature. There is first the decline in feed utilization, in net energy per unit feed with increasing feed intake (Sect. 5.2). Secondly, there may be a decline in the energetic efficiency of the entire milk-producing mechanism with increasing lactation rate above a certain production level similar, for example, to the decline in the energetic efficiency of an automobile with increasing driving speed above about 30 miles an hour (Ch. 24). Table 5.2 appears to indicate that the gross energetic efficiency of milk production tends to decline if increased milk production is brought about by feeding beyond certain levels.

The *gross* energetic efficiency of milk production may be estimated (Ch. 21) by dividing the Calorie equivalents of the milk yield (pound *FCM* \times 340) by the Calorie equivalent of the feed consumed (pounds *TDN* \times 1814). The *net* energetic efficiency of milk production may be similarly estimated by dividing the Calorie equivalent of the milk yield by the Calorie equivalent of

the feed consumed *above the maintenance level*. There is, of course, a large error in estimating maintenance—distinct from production—of a producing animal, and for this reason the *net* energetic efficiency of milk secretion is less close to reality than is the gross efficiency.

TABLE 5.2. Milk Production as a Function of *TDN* and Grain Consumption.

Feeding level % of Haecker's standard above total maintenance		<i>TDN</i> consumed million Cal	<i>TDN</i> consumed above maintenance million Cal.	Milk produced million Cal.	Energetic efficiency of milk products	
					gross (%)	net (%)
96	91	10.256	4.256	2.593	25.3	60.4
101	102	11.096	5.132	2.783	25.1	54.2
105	110	11.931	5.963	3.000	25.1	50.3
110	120	12.937	6.973	3.196	24.7	45.8
114	128	13.661	7.697	3.325	24.3	43.2
116	138	14.329	8.364	3.388	23.7	40.5

The above values were computed from the following data by Jensen *et al.*⁹

Feeding level % of Haecker's standard above total maintenance		No. lactations	<i>TDN</i> consumed (lbs)	<i>TDN</i> consumed above maintenance (lbs)	Milk (<i>FCM</i>) produced (lbs)	Grain consumed (lbs)
96	91	65	5654	2366	7626	1722

					Milk sells for 2.6¢ per lb			Milk sells for 3¢ per lb		

The gross and net energetic efficiencies of milk production as function of plane of nutrition in Table 5.2 were estimated from the previously cited report by Jensen and associates.⁹ The increase in *TDN* consumption was attained by increasing the grain allowance; the roughage was fed *ad libitum* in all cases.

Jensen's original summary, from which the efficiency estimates were made, is also listed in Table 5.2. Following Jensen's summary table are listed simi-

lar data by Borland¹⁵ and associates in which, however, not the *TDN* consumed, but only grain supplement consumed is given. As previously noted, the increased *TDN* consumption is achieved by increasing the grain allowance, the animals being always allowed all the roughage they will consume. Borland's data include milk produced per pound grain offered, and the money values involved. While the milk return per pound grain decreases with increasing grain offerings, the profits per cow—and, therefore, per herd—increase with increasing grain feeding, that is, when the cost of grain and return for milk are as here given. The profits, of course, vary with the relative market prices of milk and grain. The higher the milk price and the lower the grain cost, the greater the profit on increased grain feeding. If the expenses of housing, labor, and management were taken into consideration, the higher grain levels would show higher profits (Ch. 22). Since the feed (and bedding) item constitutes only about 50 per cent of the cost of milk production, the remaining 50 per cent of the cost goes for labor (about 30 per cent) and other expenses (20 per cent); and the labor and other overhead expenses are virtually the same for high and low-milking cows. It is possible, however, that the high feeding level may have an unfavorable long-range effect, such as development of mastitis and, in general, acceleration of the senescence process (Ch. 18), analogous to the unfavorable effect of overworking a horse, or driving machinery above certain speeds. Paraphrasing Jensen, it is easy to obtain large crop yields by the lavish use of fertilizer, but does it pay, both this year and in the long run? The time and economic elements complicate all the conclusions.

The above summaries demonstrate that increased *TDN* consumption, brought about by increased grain allowance, tends to increase the milk yield, but at decreasing increments with successive feed units in accordance with the principle of diminishing increments. Jensen fitted the Spillman diminishing-returns equation $W = A(A - R^n)$ to these data, as shown in Fig. 5.8. The satisfactory fit of this equation does not prove anything, since the range of the data is so narrow that a linear or parabolic equation would probably fit equally well. The theory and, therefore, the fitting of the equation of the principle of diminishing increments to these data is, however, reasonable.

An important feature of Jensen's data is the difference in response of "good" and "poor" cows to increased grain allowances, as illustrated by Fig. 5.9. This, of course, is what might be expected: high milk production is not only the result of high feed consumption but also of the ability or the competence of the cow to convert the extra feed into milk.

The following table from Borland is cited by way of simple summary of the discussion of diminishing milk increments with increasing grain allowance.

¹⁵ Borland, A. A., Bean, A. L., and Jones, P. D., "The relation of grain feeding to milk production", Pennsylvania Agric. Exp. Sta. Bull. 424, 1942.

Grain fed % of Haeccker's standard (%)	Milk (FCM) yield per lb of grain fed (in addition to <i>ad libitum</i> rough- age, etc.) (lbs)
90	1.4
100	1.1
110	1.0
120	0.8
130	0.6

It may be noted¹⁶ that dairy animals produce about 80 per cent as much milk energy on an exclusive, good, roughage ration as on a roughage ration

Fig. 5.8a—Feed input and milk output of all cows fed at six different levels of feeding at nine stations conducting experiments in series I and II.

supplemented with about 1 lb grain per 6 lb milk (FCM), and that it generally pays to feed at least 1 lb grain to 5–6 lbs milk.

Why is an *ad libitum* roughage ration inferior to a roughage and grain ration? Probably because of physical limitations in handling sufficient roughage to

¹⁶ Cf. Jensen²; Borland¹⁵; Woodward, T. E., Shepherd, J. B. and Graves, R. R., Report U.S.D. Agr. Misc. Publ. 179, 1933. Sherwood, D. H., and Dean, H. K., "Feeding alfalfa hay alone and with concentrates", Oregon Agr. Exp. Sta. Bull. 380, 1940. Headley, F. B., "Economics of feeding hay and grain to cows", Nev. Agr. Exp. Sta. Bull. 140, 1935. Graves, R. R., et al., "Milk production on four plane of feeding U.S.D. Agr. Tech. Bull. 724, 1940.

supply the needed net nutrients for a high level of milk production, since one pound of grain is equivalent in net energy to several pounds of roughage. Hence the greater the lactational capacity of the cow, the greater should be the ratio of grain to roughage. It is, moreover, probable that a pound of *TDN* in the form of grain has a higher nutritive value than it has in the form of roughage. In other words, roughages may be over valued when represented in terms of the conventional *TDN* (Sect. 2.3).

The general conclusion follows that the greater the lactational capacity of the cow the greater the effect of the grain supplement on milk production

Fig. 5.8b—Chart, based on the smoother data of experiment series I and II combined, and roughage alone of series II, nonpasture stations after adjustment of series II data for difference in basic producing ability of the cows.

(Fig. 5.9). This is an illustration of a broad principle: good environment is good only in relation to the organism's ability to benefit thereby (Ch. 10).

5.5: The principle of diminishing increments and egg production efficiency. Fig. 1.1 (page 3) indicates that the gross efficiency of egg production increases at diminishing increments with increasing egg-production level associated with inherent differences in production capacity. The mechanism of this relation is similar to that of increasing gross efficiency of milk production at diminishing increments associated with inherent differences in lactational capacity, explained in the preceding section.

While no data are available, there is no doubt that egg production is related exponentially to feed consumption in the same manner that milk production is associated with feed consumption, that is, in accord with the principle of diminishing increments.

5.6: The principle of diminishing increments and muscular-work efficiency. Figs. 1.3 and 1.4 (p. 7 and 9) and many charts in Ch. 24 indicate that the gross efficiency of muscular work increases with increasing work rate, but at diminishing increments, in the same manner as the gross efficiency of milk or egg production increases with increasing productive level and for the same reason:

Fig. 5.9—Input-output curves of cows of different inherent productivity at the nine experiment stations.

the greater the speed of work the less the maintenance cost per unit product, approaching net efficiency (not including maintenance) as limit.

The fact that the gross efficiency of muscular work increases with increasing rate of work does not mean that it is desirable to work at a high rate; increasing the rate of work beyond a reasonable level tends to injure the animal and shorten its productive life. There is, above a certain productive level, an incompatibility between immediate and long-range efficiency. The same appears to be true of other productive processes such as milk and egg produc-

tion; the span of the productive life is an important element in the overall production and profit pictures.

5.7: Summary and appendix. This chapter discusses the common-sense and mathematical aspects of the very broad principle of diminishing increments. This principle is illustrated in detail by the influence of the plane of nutrition on digestibility, metabolizability, and especially on the net energy values of rations. Increasing the plane of nutrition (above the maintenance level) increases the losses per unit feed, and therefore decreases the net energy per unit feed. In other words, the net-energy intake increases less rapidly than the gross-energy intake, in accordance with the principle of diminishing increments (Fig. 5.1).

The net energy value per unit feed is thus not constant but varies with the plane of nutrition and with many other factors. Armsby's published net energy values¹⁷ do not, therefore, have the constant significance that they were originally given. Armsby (like Kellner) assumed a direct proportionality between net energy and gross energy consumption, an assumption contrary to the principle of diminishing increments.*

For practical purposes, however, it is legitimate to assume average values. We conclude from the analysis of the data that the average cattle ration employed, which had a combustion value of 2000 Cal/lb (4.5 Cal/g) had an average apparent digestible-energy value of about 1600 Cal/lb (3.2 Cal/g) of the original feed, a metabolizable energy of 1200 Cal/lb (2.7 Cal/g) of the original feed and a net-energy value of about 1000 Cal/lb (2.2 Cal/g) of the original feed (see lower table in Sect. 2.6). The *approximate* apparent digestible energy of the given feed is thus about 70 per cent of the gross energy; the *approximate* metabolizable energy of the given feed is about 60 per cent of the gross energy, and the *approximate* net energy value of the given cattle ration is about 50 per cent of the gross energy. The *exact* values, however, vary with the plane of nutrition and many other factors discussed in the text (Table 5.1 and Figs. 5.3 and 5.4).

* Illustration of Armsby's direct-proportionality or linear method for computing the heat increment of feeding, the fasting heat production, and the net energy of feeds:

Period	Dry matter in feed (kg)	Heat produc- tion (Cal)	Heat increment (Cal/kg dry matter)	Extrapolated fasting mainte- nance (Cal.)
1	3.6674	8224	706	5635
2	5.4676	9495		
Difference	1.8002	1271	($= 1271/1.8002$) ($= 8224 - (706 \times 3.6674)$)	

Different amounts of feed were allowed during periods 1 and 2, the corresponding heat productions were measured and the difference in heat production ($9495 - 8224 = 1271$ Cal) was divided by the difference in feed consumption ($5.4676 - 3.6674 = 1.8002$ kg) to obtain the average heat increment per unit feed increment ($1271/1.8002 = 706$ Cal/kg). The net energy was then computed by deducting the heat increment from the metabolizable energy. The fasting heat production was computed by deducting the product of the heat increment per kg feed and the number of kg feed consumed, from the heat production at a given plane of consumption [$8224 - (706 \times 3.6674) = 5635$].

¹⁷ Armsby, H. P., "The Nutrition of Farm Animals", 1917.

While discussing the general principles relating net to gross energy intake, we learned many important details. Thus (Fig. 5.3) the apparent heat increment, or *SDA*, of feeding, as conventionally defined, ranges in cattle from 3 per cent of the *gross energy* at 0.5 maintenance to about 20 per cent at full feed; or it ranges from 8 per cent of the *TDN energy* at 0.5 maintenance to 30 per cent of the *TDN energy* at full feed; or it ranges from about 8 per cent of the *metabolizable energy* at 0.5 maintenance to 38 per cent of the metabolizable energy at full feed. The apparent range is less striking for the other excreta. The various energy categories of feed declined correspondingly with increasing plane of nutrition. Thus the digestible energy declines from 3.3 Cal/g feed at 0.5 maintenance to 3.0 Cal/g gross feed at full feed; the metabolizable energy declined from about 3.0 Cal/g feed at 0.5 maintenance to about 2.5 Cal/g feed at full maintenance; the net energy declined from about 2.3 Cal/g feed at 0.5 maintenance to 1.6 Cal/g feed at full maintenance. For purposes of computing efficiency, it is assumed in this book that 1 g *TDN* is equivalent to 4 Cal, or 1 pound *TDN* to 1814 Cal, corresponding to the 4 Cal/g of metabolizable energy, or physiologic fuel value, employed in computing human food values. The actual metabolizable energy per unit *TDN* of the usual cattle feeds appears to be less than those here given, of the order of 1600 Cal per pound *TDN*.

An interesting aspect of this analysis is that while the *apparent* digestibility of the rabbit ration (65 per cent of the gross energy) is about 8 per cent below that of the cattle ration (73 per cent of the gross energy), the apparent metabolizable and net-energy values are the same for both species (the metabolizable energy is about 60 per cent of the gross energy and the net is about 50 per cent of the gross energy). This apparent 8 per cent difference in digestibility is attributed to an 8 per cent greater methane production in cattle than in rabbits, and because the methane energy is conventionally counted as part of the digestible but not of the metabolizable energy. It thus appears that the rabbit is a good assay animal for estimating the metabolizable- and net-energy values of cattle rations, but that the *apparent* digestibility of the ration is, perhaps, 8 per cent less in rabbits than in cattle. The *real* digestibility is probably the same in both.

A curious aspect about the methane and urinary energy is that the percentages of both appeared to decrease with increasing plane of nutrition. The urinary energy appeared to be about 5 per cent of the gross feed energy at 0.5 maintenance and 2-3 per cent at full feeding. The methane energy declined from about 10 per cent at 0.5 maintenance to about 8 per cent at full feed.

The principle of diminishing returns was also applied to normal growth (successive time units elicit ever smaller weight gains), to egg production, to muscular work, and especially to milk production. The gross energetic efficiency of these processes increases with increasing rate of productivity

because of declining maintenance cost per unit product; but the increasing gross efficiency occurs at declining increments because the gross efficiency approaches net efficiency (not including maintenance) as a limit.

The increase in milk production at decreasing increments with increasing grain consumption was explained by a different mechanism. Whatever the mechanism, the fact is that by increasing the grain allowance to the limit, milk production may be increased 15 to 20 per cent above the level of cows fed in accordance with the usual standards; and that milk production may be decreased by about 20 per cent on reducing the customary feeding standards by 20 to 30 per cent. The relative profitableness of heavy and light grain feeding depends, of course, on (1) the relative feed and milk prices and (2) the relative abilities of individual cows to utilize the extra grain allowance advantageously. The lactation problem will be discussed in greater detail in Chapters 21 and 22. The relative gross energetic efficiencies of various transformations (growth, milk production, egg production, muscular work) in different species and at different ages are discussed in Chapter 3.

Chapter 6

Metabolic Catalysts in the Efficiency Complex: Enzymes, Minerals, and Vitamins in Biologic Oxidations

Among the most fundamental of the dynamic chemical events related to life are the oxidations which yield energy to the cell. *F. G. Hopkins*

Oxidation was thought a few decades ago to be exceedingly simple. The organic molecule was burned and energy produced much as in the steam engine. There was no problem at all. Since then the problem of oxidation has developed into a wide and fruitful field of scientific inquiry. *Albert von Szent-Györgyi*

There is a substance which even in very small quantities is of paramount importance to nutrition. If this substance is absent the appetite is lost and with apparent abundance the animals die of want. *C. A. Pikelharing*, 1905.

6.1: Introduction. The primary purpose of this book is to present quantitative analyses of metabolic processes of the organism *as a whole* in relation to the energetic efficiency of agriculturally productive transformations. This discussion would, however, fail in perspective if it overlooked the mechanisms of these processes. It is not the purpose to discuss the problems of biologic oxidation and catalysis in detail, but to outline in general fashion the contemporary theories and to point out the unity in what appears to be a confusing diversity of enzymes, vitamins, minerals, and hormones in biologic oxidation processes.

One aspect of biologic oxidation is that outside the body foodstuffs may be preserved for centuries, as illustrated by the good state of preservation of cereals recently found in the tombs of Egyptian kings, while within the body the nutrients are oxidized stepwise in accordance with needs of the organism. What are the mechanisms wherewith the body times the oxidation of the nutrients at the given rates in accordance with the needs of the organism?

Needless to say, the efficiency of biologic transformations is dependent on the exquisite timing and completeness of the oxidative reactions. Thus, to cite typical illustrations, the lack of thiamine (vitamin B₁) in the diet of species requiring it retards the oxidation rate of pyruvic acid and, therefore, leads to its accumulation in the tissues, which results in the well-known beriberi syndrome. Decrease of oxygen supply to the heart leads to angina pectoris, and lack of oxygen supply to the kidney (due to narrowing of blood vessels) leads

to high blood pressure¹. Intake of certain selenium compounds in the feed of farm animals leads to "alkali disease" in cattle due to the destruction of certain oxidation catalysts². Lack of the necessary traces of copper, zinc, magnesium, iron, cobalt in animal feeds causes deficiency of oxidation catalysts in the body with serious symptoms variously named, depending on locality and species, such as salt sickness, marasmus, perosis, and so on. Whenever the oxidation process stops short of the final oxidation products H_2O and CO_2 , as for example when fat oxidation stops with the aceto-acetic acid stage, or carbohydrate oxidation with the pyruvic acid, lactic acid or alcohol stage, the energetic efficiency of food utilization is reduced by this much, in addition to development of the intoxications with corresponding pathologic conditions. Many disabilities associated with aging may be viewed as due in part to declining ability of the circulatory system to supply the tissues with oxygen and of the declining ability of the tissues to utilize the oxygen at a sufficiently rapid rate.

It is generally known³ that food utilization is greatly depressed when the diet is deficient in vitamins. The depression of food utilization may be only apparent, due to anorexia⁴ (diminished appetite), or real, as when the animals are pair-fed, and consume the same amounts of foods in the absence of anorexia. Thus Sure⁵ reported (Fig. 6.1) that young rats, not suffering from anorexia, fed a diet deficient in riboflavin (vitamin B_2) gained about 6 g in 125 days, whereas litter mates receiving the same kind and amount of food for the 125 days but supplemented with 20 μg riboflavin gained about 60 grams—a ten-fold gain! Analogous results were reported by Shaw and Phillips⁶ and others.

This difference in food utilization results in part from differences in completeness of food oxidation, as riboflavin is an essential component of about a dozen flavoprotein oxidation enzymes. It is known that decrease in dietary riboflavin decreases the corresponding flavoprotein enzymes, such as riboflavin-adenine dinucleotid⁷, *d*-amino acid oxidase, or xanthin oxidase⁸.

The problem of the mechanism and timing of biologic oxidation, no doubt a very old one, is new in its experimental aspects, beginning with the discov-

G., "Biological Oxidation", 1939. Bernheim, F., "Interactions of Drugs and Cell Catalysts", Burgess, 1942.

(b) *fermentative*, in which atmospheric oxygen does not participate, yielding incompletely oxidized products, such as pyruvic acid, lactic acid, acetic acid, alcohol, and so on. Corresponding to the respiratory and fermentative types of oxidation there are two types of organisms: (a) *aerobic*, depending for their energy on oxidation by atmospheric oxygen, and (b) *anaerobic*, depending for their energy on anaerobic oxidations. But there is no sharp dividing line between the two.

Thus, Pasteur¹⁷ discovered that a plentiful oxygen supply causes yeast to transfer from the anaerobic to the aerobic method of oxidation ("Pasteur effect"¹⁸); and Fletcher and Hopkins¹⁹ discovered that muscle of aerobic animals may be stimulated to work in the absence of oxygen, yielding lactic acid (a product of anaerobic oxidation) rather than CO₂ and H₂O.

Fletcher and Hopkins exercised an isolated muscle. But the same appears to be true in intact animals. Thus it will be shown in Chapter 24 that during *prolonged* hard work, horses and men may expend about eight-fold the energy at rest, whereas during *very intense* muscular work (which cannot be prolonged because of rapidly onsetting fatigue), they may expend 100 times the energy at rest. This does not mean that the rate of oxygen consumption is increased 100 times. During very intense exertion, when the oxygen supply is too slow for aerobic oxidation, the energy is obtained anaerobically, from anaerobic energy reservoirs. Under such conditions the animal is said to go into *oxygen debt*. Lactic acid accumulation is associated with anaerobic oxidation in animals. Hill²⁰ reported an athlete who liberated over 4 g of lactic acid per *second* while running at the rate of 11 yards per second. During the 15 seconds of sprinting, about 50 g (1 $\frac{3}{4}$ oz) of lactic acid was liberated, and the *oxygen debt* reached 7 to 8 liters. But the oxygen debt is known to have risen in a 70-kg athlete to 19 liters, with the liberation of 114 grams ($\frac{1}{4}$ lb of lactic acid²¹).

Regardless of theories, the *fact* is that the "oxygen debt" is associated with *increase* in concentrations of lactic acid and phosphoric acid (and perhaps pyruvic acid) and also with a *decrease* in concentration of phosphocreatine and adenosine pyrophosphate. The "recovery" (at rest) phase is associated with a reverse process, *decrease* in concentration of lactic and phosphoric acids and *increase* in concentration of phosphocreatine and adenosine pyrophosphate^{22, 23}. It thus appears that when aerobic oxidation is inadequate, the

energy is obtained by cleavage of phosphocreatine (also called phosphagen and creatine phosphate) to creatine and phosphate.

During recovery, phosphocreatine is resynthesized at the expense of another energy source. The recurrent synthesis and cleavage of phosphocreatine and adenopyrophosphate is thus analogous to recurrent charging and discharging of a battery. Phosphocreatine, like a battery, is an energy reservoir, discharged and charged in accordance with the conditions and needs. Lohman discovered that adenyly pyrophosphate is the phosphate carrier; it furnishes the phosphate for phosphorylation of the creatine, as indicated by the Lohman reaction:

The energy for resynthesis (charging) of the phosphocreatine may come from the oxidation of glycogen to CO_2 and H_2O

and perhaps from fermentation (glycolysis) of glycogen to lactic acid.²⁴

Lactic acid formation is not believed to be the *direct* energy source for anaerobic muscular contraction, since the lactic acid forms *after* the work of contraction²⁵, as indicated by the observation that muscular contraction may occur and carbohydrate may be oxidized after poisoning the muscle with iodoacetate when lactic acid formation is blocked^{26, 27}, and that up to a certain level the oxygen debt is incurred without increase in blood lactate^{26, 28}. According to Dill²⁸, the recovery period is, therefore, made up of (1) an alactacid and (2) a lactacid phase.

6.3: Oxidation-reduction potentials and biologic oxidation. It was said above that oxidations are of two kinds: (1) aerobic, involving atmospheric oxygen, and (2) anaerobic, in which oxygen does not participate. In other words, while oxidation may mean combination with oxygen, it is not necessarily such. More often oxidation means the loss of hydrogen, or dehydro-

genation. But oxidation is not confined to gain of oxygen and/or loss of hydrogen; and reduction is not confined to loss of oxygen or gain of hydrogen. Broadly defined, oxidation is loss of electrons, and reduction is gain of electrons. Thus ferrous iron, Fe^{++} , is oxidized by the loss of an electron, e :

or ferric iron, Fe^{+++} , is reduced by the gain of an electron, e :

This oxidation, or reduction, may involve oxygen

or may not involve oxygen

The experimental work on biologic-oxidation mechanisms is concerned mostly with anaerobic processes often conducted near freezing temperatures because the aerobic processes at 37°C are too rapid for detailed observation and analysis, or by "dissecting out" metabolic stages by differentially acting metabolic inhibitors or poisons, such as iodoacetates, fluorides, cyanides, and so on. Because of the difficulty of observing the details of normal aerobic processes, it is not definitely established that most of the products formed in tissues under anaerobic conditions, such as pyruvic acid, lactic acid, alcohol²⁹ and so on, are necessarily formed under aerobic conditions of rest. It is certain, however, as indicated in the preceding section, that when the circulatory oxygen supply is inadequate, energy expenditure is associated with increased concentration of lactic acid, a typical product of anaerobic oxidation; and that the absence of dietary thiamine involved in pyruvic acid oxidation leads to the accumulation of pyruvic acid³⁰, a typical product of anaerobic oxidation. Moreover, tissues or systems normally poorly supplied with oxygen tend to have appreciable concentrations of lactic acid. Spermatozoa³¹ regularly obtain energy by glycolysis (fermentation of glucose to lactic acid), and there is no doubt that there is more or less glycolysis in other animal systems.

While the definition of oxidation as loss of electrons and reduction as gain of electrons is an old one in general chemistry, its elucidation and general acceptance in biology is recent. It is due largely to Mansfield Clark³², who defined dehydrogenase activity as the taking up and passing of electrons.

When a solution of Fe^{++} is connected with one of Fe^{+++} , an electromotive

²⁹ There is normally from 0.05 to 0.12 mg alcohol per 100 g brain, from 0.09 to 0.23 mg alcohol per 100 g liver, from 0.04 to 0.14 mg alcohol per 100 g kidney, and so on [Harger, R. N., and Gross, A. L., *Am. J. Physiol.*, **112**, 374 (1935)].

force is created, the magnitude of which depends on the relative concentrations of the two ion forms. Potential differences are likewise set up if solutions of any two electrolytes are connected. The voltage reading will depend on the relative "electron pressures" of the respective elements. This way, the elements were arranged in an electromotive series, in some such order as the following: Li, Rb, K, Sr, Ba, Ca, Mg, Al, Mn, Zn, Cr, Fe, Cd, Co, Ni, Sn, Pb, H, Sb, Bi, As, Cu, Hg, Ag, Pt, Au, which is the order of ease with which the elements donate their electrons, that is, become oxidized. The electromotive potentials of the inorganic elements are known. The potential driving the reduction of H^+ by Zn^0 in the reaction,

for example, is definitely known from electrode potential measurements.

Moreover, the free energies of the reactions are known [Sect. 2.1.2 and eq. (2.5)]; the free energy, ΔF , of a reversible galvanic cell is related to its potential, E , by the equation

$$\Delta F = -nFE \quad (2.5)$$

and the potential, E_h , with respect to the hydrogen electrode taken as zero, is computed from the equation

$$E_h = E_0 + \frac{RT}{nF} \ln \frac{\text{concentration oxidized form}}{\text{concentration reduced form}}$$

This equation was previously cited [eq. (2.8), sect. 2.1.2]. E_0 is the characteristic constant of the system when the half cell of the given substance is connected to a hydrogen electrode, that is, to platinum sponge saturated with hydrogen gas, when the concentration of the oxidized form is equivalent to the concentration of the reduced form and when the pH is 7.0 at 30° C; R is the gas constant, 8.31507 volt coulombs; n , number of equivalents, or electrons, freed when the reduced form is changed to the oxidized form; F is the Faraday (96,500 coulombs); \ln represents the natural logarithm.

Living cells contain many substances which, like the above inorganic elements, may be arranged in an electromotive series. The electromotive-series arrangement of substances in the body cannot be as precise as that of inorganic elements acting in glass beakers because of the enormously greater complexity of the thermodynamic equilibria in the body. But such EMF arrangements are useful for prediction purposes.

There is a large literature³³ on the oxidation-reduction potentials of various biological substances—enzymes and substrates—involved in biologic

³³ For review, see: Ball, E. G., in "Symposium on Respiratory Enzymes", University of Wisconsin Press, 1942; Barron, E. S. G., *Physiol. Rev.*, **19**, 184 (1939); Stephenson, M.¹⁶; Kalckar, H. M., 1941¹⁶; Gillespie, L. J., *Soil Sci.*, **9**, 199 (1920); Clark, W. M., *Pub. Health Rep.*, **38**, 443 (1923); *Medicine*, **13**, 207 (1934); *J. App. Physics*, **9**, 97 (1928); Clark, W. M., "Determination of Hydrogen Ions", 1928; Michaelis, L., "Oxidation-reduction Potentials", 1930. Hewitt, L. F., "Oxidation-reduction potentials in bacteriology and biochemistry", London, 1935; Shaffer, P. A., *J. Phys. Chem.*, **40** (1936); Wurmser, R., "Oxydations et reductions", Paris, 1930.

oxidations. Many artificial dyes, such as methylene blue, made famous by Thunberg, who used it as an oxidizing agent in biologic systems (in place of oxygen), change color at certain oxidation-reduction zones and are thus used as indicators for measuring O-R potentials. When thus arranged in an electromotive series, oxygen is on top, with the highest positive voltage, and hydrogen at the bottom, with the highest negative voltage. The various biologically active substances come in between.

Nutrients are, of course, reducing agents; by this we mean that they tend to be oxidized, to lose their hydrogens, and these, therefore, come low in the electromotive series, near hydrogen, which is assigned a voltage of about -0.4 for pH 7.0. The hydrogens (and electrons) from the substrate are transported, *stepwise*, from one carrier or mediator, or from one H transport system or H-acceptor to the other standing above it in the EMF series, until finally the substrate hydrogen reaches the atmospheric oxygen standing at the top of the series, forming water, the final step in the oxidation process in aerobes. The essential oxidation feature is the combination of hydrogen with oxygen (or the transfer of electrons from hydrogen to oxygen), not the combination of carbon with oxygen.

As previously noted, the position of the substrate fuel in the EMF series is low, near hydrogen, with a voltage reading of about -0.4 . Then come³⁴ the pyridinoprotein enzymes (voltage about -0.3), followed by the flavo-protein enzymes (voltage about -0.1 to -0.2), followed by the iron-porphyrin enzymes, namely cytochrome-*b* (-0.04), cytochrome-*c* ($+0.27$), and cytochrome-*a* ($+0.29$); followed by the cytochrome oxidases ($+0.4$ to $+0.6$) and, finally, oxygen ($+0.8$).

The stepwise reductions, that is the successive passing of the hydrogens or electrons, is thus from the substrate to the pyridine nucleotides, to the flavoproteins, to the cytochromes and cytochrome oxidases, and finally to oxygen. In other words, the substrates reduce the pyridinoprotein enzymes, which reduce the flavoprotein enzymes, which reduce the porphyrin enzymes, which reduce the atmospheric oxygen. This is an oversimplified diagram, but it may give a general idea of the way biologic, stepwise oxidations occur.³⁵

The first step in oxidation is the phosphorylation (combination with phosphoric acid) of the glycogen or glucose, forming hexose phosphate; this splits into triose phosphates; then into glyceraldehyde, as indicated in the following over-simplified diagrams for oxidation of hexose and for oxidative deamination of amino acid.

³⁴ Cf. Ball, E. G.³³

³⁵ For another aspect, see Szent-Györgyi, A., "Towards a new biochemistry", *Science*, **93**, 609 (1941).

These and similar oxidoreduction reactions are catalyzed by enzyme systems, of which the following are outstanding. (1) Phosphorylases, catalyze phosphorylation, that is, combination of phosphate with glycogen, starch, glucose, and so on, preliminary to cleavage.³⁶ (2) Decarboxylases, exemplified by carboxylase, which splits CO₂ from α-keto acids converting them to aldehydes and CO₂, and by carbonic anhydrase which splits H₂CO₃ into CO₂ and H₂O. (3) Dehydrogenases typified by lactic acid dehydrogenase, which converts lactic acid to pyruvic acid; amino acid oxidase³⁷ or dehydrogenase, which converts α-amino to α-keto acids; succinic acid dehydrogenase, which converts succinic acid to fumaric acid; cytochrome reductase, which converts reduced coenzyme II to oxidized coenzyme II; and alcohol dehydrogenase, which converts alcohol to acetaldehyde. (4) Oxidases, including cytochrome oxidase (also called Warburg's enzyme or *Atmungsferment*, Ehrlich's enzyme, and indophenol oxidase), which catalyzes the oxidation (by oxygen) of reduced cytochrome-c to (oxidized) cytochrome-c (equations given below); tyrosinase, which oxidizes tyrosine to black pigments (seen in darkening of cut potato or apple); and polyphenol, which convert polyphenols to quinones. (5) Transaminases³⁸, or aminophorases, which catalyze intermolecular transfer of the amino group and a hydrogen group as, for example, the transfer of paired amino and keto acids to corresponding keto and amino acids. The place of vitamins and minerals in these biocatalytic systems—enzymes and coenzymes—is discussed below and also in Chapter 20.

The following examples indicate empirical applications of oxidation-reduction (O-R) potentials in the dairy industry. The O-R of milk normally drifts down with time after milking, probably due to the oxygen removal by aerobic bacteria or by other oxidations. If, however, copper or iron is added (the potency of copper is ten times that of ferrous³⁹ iron), the O-R potential rises, and oxidized flavors develop in parallel⁴⁰. On the other hand, tin and aluminum lower the O-R potential of milk, and probably retard the

flavor production⁴¹. Changing dairy cows from dry to fresh feed decreases the O-R⁴² and reduces development of oxidized flavors. Summer milk does not develop oxidized flavors as readily as winter milk, and the O-R potential of summer milk is below that of winter milk⁴³. This may be associated with the increased ascorbic acid content in summer milk: increasing ascorbic acid (reduced form) decreases the O-R potential, as can be proved by adding crystalline ascorbic acid to milk³⁹. In brief, anything which reduces the O-R potential of milk also reduces the production of oxidized flavors in milk⁴⁴.

Off flavor in plant products, such as a hay-like flavor in stored raspberries, is probably also the result of oxidations similar to those in milk, butter, and ice cream. The removal of oxygen, or what is more practical the maintenance of an atmosphere of high N₂ or CO₂ concentration, is often a means of preserving food products by reducing oxidation processes initiated by the various catalysts in the tissues.

6.4: Interrelations between minerals, vitamins, enzymes, and hormones in biologic oxidations: an illustration of unity in diversity. Keilin⁴⁵ recognized the identity in what were considered as several distinct enzymes, namely Warburg's enzyme (*Atmungsferment*), indophenyl oxidase (Ehrlich's enzyme, 1885), and cytochrome oxidase.

Szent-Györgyi⁴⁶, and also King⁴⁷, recognized that the coenzyme *l*-ascorbic acid,

is identical with the antiscorbutic factor, vitamin C. This discovery of the relation between a vitamin and enzyme in biologic oxidation is important partly because it focuses attention on the convergence of several apparently different kinds of investigations into one, namely biocatalysis. Szent-Györgyi was awarded the 1937 Nobel Prize in medicine for this and related discoveries.

6.4.1: Definitions and interrelations. Vitamins are organic catalysts, or essential components of catalysts, in biologic oxidations and related processes.

Vitamins are *exogenous catalysts*, externally provided; hormones and enzymes are *endogenous catalysts*, internally produced by the body.

There is, however, no dividing line between the exogenous and endogenous catalysts. Thus ascorbic acid (vitamin C) is an *exogenous catalyst* to primates

and guinea pigs: they must ingest ascorbic acid; they cannot synthesize it. Other animal species examined are not dependent on dietary ascorbic acid—to them ascorbic acid is an *endogenous catalyst*; they can synthesize it. Of course, green plants synthesize ascorbic acid, so that it is not a vitamin to plants.

Moreover, even the self-sufficient animals are not always self-sufficient. Low vitality, due, for example, to low vitamin A intake⁴⁸, or to increasing age⁴⁹, results in low ascorbic-acid production, in which case ascorbic-acid administration is indicated.

Hormones and enzymes are endogenous catalysts; however, the building stones of these endogenous catalysts are derived from food, an exogenous source. Thus thyroxine, the powerful thyroid biologic-oxidation catalyst, is produced from food components, from the mineral iodine and from the amino acid tyrosine, which the body must obtain from food. Similar statements may be made of other hormones, such as adrenaline, another tyrosine derivative (Ch. 7).

Broadly speaking, an oxidoreduction *enzyme* is a protein-complex catalyst of high molecular weight, not dialyzable, and denatured by heat. The enzyme contains, or is associated with, a *coenzyme* which is of relatively small molecular weight, dialyzable, and may be thermostable. The "active part" of the enzyme or coenzyme is the *prosthetic group*.

Now some vitamins serve as prosthetic groups in enzyme systems. The best known example of such vitamins is vitamin B₁, or thiamine, which is the prosthetic group of the coenzyme cocarboxylase, a pyrophosphoric acid ester of thiamine. The cocarboxylase is, in turn, the prosthetic group of the enzyme carboxylase previously mentioned, which is a pyrophosphothiamine magnesium protein¹⁵¹. This enzyme carboxylase catalyzes the decarboxylation of α -keto acids, particularly pyruvic acid. If there is deficiency of thiamine, there is also deficiency of the coenzyme cocarboxylase and of the enzyme carboxylase with the associated high level of pyruvic acid³⁰ and polyneuritis syndrome (Sect. 20.6). The reaction equations under the influence of carboxylase (decarboxylation of pyruvic acid) and dehydrogenases (conversion of triose phosphate to phosphoglyceric acid, and oxidative deamination of amino acid) were cited in the preceding section.

Vitamin B₂, or riboflavin, is similarly the prosthetic group of the coenzyme riboflavin mononucleotide, which is in turn the prosthetic group of dehydrogenase enzymes, such as Warburg and Christian's "yellow enzyme" and of the dehydrogenase enzyme cytochrome reductase, previously described. There are many riboflavoprotein enzymes catalyzing oxidation processes. The coenzyme riboflavin adenine dinucleotide is a prosthetic group, among

⁴⁸ Sutton, T. S., *et al.*, *J. Biol. Chem.*, **144**, 183 (1942).

others, of the enzyme xanthine oxidase, and xanthine oxidase and riboflavin dinucleotide decrease during dietary riboflavin deficiency⁷.

Nicotinic acid is similarly the prosthetic group of the coenzymes I and II (also known as codehydrogenases I and II and by other designations), which are, respectively, diphosphopyridine and triphosphopyridine nucleotides (containing nicotinic acid or pyridine groups, adenine, phosphoric acid, and a pentose). The pyridine nucleotides are in turn prosthetic groups of the dehydrogenase enzymes which catalyze oxidation of lactate, malate, β -hydroxybutyrate, glyceraldehyde diphosphate, citrate, glutamic acid, glucose-6-phosphate, alcohol, succinate, formate, aldehydes and other substrates previously mentioned. Some inorganic elements, such as iron, function as prosthetic groups in enzyme systems similar to that of vitamins (Ch. 20).

Phosphorylation of the substrate (glucose, glycogen, and so on) is prerequisite for all biologic oxidations, aerobic and anaerobic⁵¹. The ubiquitous participation of phosphates in biologic oxidation is, in fact, one of its most impressive features. There is a long series of phosphate esters, such as hexosemonophosphate, hexosediphosphate, glycerophosphate, phosphoglyceric ester, phosphopyruvic ester, and so on, often associated with the names of their discoverers, such as the Harden-Young ester (fructose-1,6-diphosphate), Neuberg ester (fructose-6-phosphate), Robison ester (glucose-6-phosphate), Cori ester (glucose-1-phosphate) and so on, which play an important part in oxidoreductions.

6.4.2: Minerals in biologic oxidation. As explained above, phosphate occupies a key position in biologic oxidation. Pasteur observed its importance in 1860, Harden and Young confirmed it in 1905, and it is currently under intensive investigation by the Cori, Lipmann and Meyerhof schools, and by others.

As explained in connection with phosphocreatine (Sect 6.2) some phosphate esters serve as temporary biologic energy reservoirs, analogous to charged batteries. Thus, according to Cori, the synthesis of 6 molecules of glucose phosphate is coupled, or associated, with the oxidation of one molecule of glucose. A mol of glucose phosphate, therefore, has a labile energy increment which, depending on the energetic efficiency of the process, may be as high as 115 Cal ($\frac{1}{6}$ of about 700 Cal, the free energy of glucose). This is, presumably, what Lipmann⁵¹ refers to as phosphate-ester bond energy, the main form or source of anaerobic energy as illustrated by the reactions:

⁵¹ Lipmann, F., *Advances in Enzymology*, **1**, 99 (1941). Cori, C. F., and Cori, G. T., *Ann. Rev. Biochem.*, **10**, 151 (1941). Sowden, J. C., and Fischer, H. O. L., *Ann. Rev. Biochem.*, **11**, 203 (1942). Meyerhof, O., *Cold Spring Harbor Symposia on Quantitative Biology*, **3**, 239 (1941). Cori, G. T., Colowick, S. P., and Cori, C. F., *J. Biol. Chem.*, **123**, 375 (1938). Colowick, S. P., Welch, M. S., and Cori, C. F., *Id.*, **33**, 359, 641 (1940). Kalckar, H. M., *Biol. Rev.*, **17**, 28 (1942), and *Enzymologia*, **6**, 143 (1939).

As the value of the equilibrium constant, K , is⁵² about 40 at 38°C, we have the equation

$$\Delta F^\circ = -RT \log K = -4.58T \log K = -4.58 \times 311 \times \log 40 = -22.8 \text{ Cal}$$

The phosphate group also catalyzes the oxidation and transport of fats⁵³. Other inorganic elements may participate in the oxidation of fat and perhaps in its transformation to carbohydrate⁵⁴.

Pasteur also observed that magnesium has an important function in yeast fermentation, and it appears from the work of Cori, Lohmann, Ochoa, and others that Mg^{++} , Mn^{++} , and perhaps Co^{++} , may activate cozymases, dehydrogenases, carboxylases, phosphatases, phosphoglycomutases, cholestori-nases, and that Mg is involved in the phosphorylation of enzyme systems. Carboxylase is a diphosphothiamine-magnesium protein⁵⁵.

Probably because of its other activation effects, such as that on bone phosphatase⁵⁶, manganese deficiency, as observed on chickens, leads to leg-bone malformations, called perosis⁵⁷. However, other deficiencies, such as of biotin and choline, also lead to perosis⁵⁸.

Manganese has other functions⁵⁹. Its deficiency in young rats leads to testicular degeneration⁶⁰, subnormal vitality of the fetus and the new born⁶¹, and abnormal maternal behavior including unsatisfactory lactation⁶². Manganese deficiency also leads to a profound depression of hatchability of eggs (5 per cent of normal when the manganese in the ration is reduced to 40 ppm) and the embryos show chondrodystrophy⁶³. Manganese may play an important part in the synthesis of ascorbic acid⁶⁴.

Iron is another conspicuous inorganic element involved in biologic oxidation. It is the prosthetic group of the hemins. Hemoglobin, the red pigment in the blood, is the best known heme complex. The body of the average adult man contains about 6 liters (or quarts) of blood; the blood contains about 160 grams hemoglobin per liter; the red blood cells contain about 32 per cent hemoglobin; hemoglobin contains about 0.33 per cent iron. The iron content of a 70-Kg human body is about 4 g.

The divalent iron atom occupies a central position in the hemin part of hemoglobin, binding, centrally, four pyrrol rings together into a tetrapyrrol complex, while four CH bridges bind the four pyrrols externally.

The hemoglobin is oxygenated in the lungs (at high oxygen pressure) forming oxyhemoglobin. The oxygen is carried along the passageways—arteries, arterioles, capillaries (low oxygen pressure)—where it is freed from its loose combination with hemoglobin, and travels across the capillary walls and membranes to the tissues and the body cells. Then it passes back to the lungs to get more oxygen, and so on. The process is usually represented diagrammatically by the equation

in which Hb represents hemoglobin and HbO₂ oxyhemoglobin.

The amount of oxygen that can be taken up per unit blood varies with the species and individual. Thus, according to Baldwin⁶⁵, the oxygen capacity per 100 cc blood is about 25 cc in mammals, 18.5 in birds, 12 in amphibia, 9 in reptiles and fishes. In animals which have the copper-containing hemocyanin* instead of the iron-containing hemoglobin, the O₂ capacity is only 2 to 8 cc oxygen per 100 cc blood. The metabolic rate of an animal is, of course, limited by the O₂ supply to the tissue, which in turn is limited by the circulation speed and the O₂ capacity of the blood.

There is a similar mechanism for removal of the CO₂ from the blood. On reaching the blood, the CO₂ combines to form BHCO₃, is carried to the lungs in association with the red cells, where H₂CO₃ is formed due to increased acidity consequent on formation of HbO₂, and is exhaled as CO₂. *Carbonic anhydrase*, a zinc-protein enzyme⁶⁶, associated with the red blood cells, catalyzes the cleavage of CO₂ from H₂CO₃ in the blood.

Hemoglobin splits into heme (or hemin, the chloride form), the non-protein part containing the iron-pyrrol complex, and globin, the protein part. Species differences are due to the differences in the protein part.

The structure of hemoglobin thus resembles that of enzymes in being an organic complex containing a protein and a prosthetic group. On removing the Fe from the heme, porphyrin⁶⁷ (hematoporphyrin, protoporphyrin) results; on removing the Mg from the corresponding chlorophyll group, porphyrin (aetioporphyrin) results.

It is interesting to contemplate the fact that chlorophyll, the green pigment in green plants, is structurally identical with hemoglobin, the red pigment in animals. They differ only in the central metal atom, chlorophyll containing magnesium instead of iron.

Another iron-containing respiratory pigment in aerobic cells, *cytochrome*, was elucidated chiefly by Keilin⁶⁸. Cytochrome resembles hemoglobin in

⁶⁵ Baldwin, E., "An introduction to comparative biochemistry", Cambridge (England), 1937. See also Redfield, A. A., "The evolution of the respiratory function of the blood", *Quart. Rev. Biol.*, **8**, 31 (1933); "The hemocyanins", *Biol. Rev.*, **9**, 175 (1933).

* *Hemocyanin* is the copper-containing *blue* (when in oxygenated but colorless when in reduced form) respiratory blood pigment in certain cold-blooded animals, especially molluscs and crustaceans, corresponding to hemoglobin. Hemocyanin carries an atom of 0 per atom of Cu. Annelids have a green and also red respiratory pigments called, respectively, chlorocruorin and hemerythrin.

having the iron-porphyrin or heme group, but the heme is combined not with globin as in hemoglobin, but with pyridine⁶⁹, and the iron is not always in the divalent form, but it exists, alternately, in two forms—ferrous and ferric.

In the presence of dehydrogenase, the metabolite is oxidized and the cytochrome reduced:

In the presence of oxygen and cytochrome oxidase, the oxidized cytochrome is regenerated:

The cytochrome is thus alternately reduced and oxidized, analogous to the way in which hemoglobin is alternately oxygenated and deoxygenated. The Fe in the cytochrome is oscillating between Fe^{++} and Fe^{+++} , transmitting electrons from H to O with the aid of cytochrome oxidase, while the Fe in hemoglobin is always in the ferrous form.

Cytochrome has been investigated in its oxidized and reduced forms most spectacularly in the bodies of insects. The scales of the insects were removed and observed under a microspectroscope. Typical 4-banded spectra appear under the spectroscope when the insect struggles and the cytochrome is reduced; the spectra disappear when the insect rests and the cytochrome is oxidized. Likewise in yeast, the spectrum appears when the air is reduced and disappears when air is supplied. In brief, the cytochrome is in the reduced form when the O_2 supply is poor, and in oxidized form when the O_2 supply is good.

The cytochrome complex was called by Warburg⁷⁰ "respiration catalyst" (*Atmungsferment*), the metal being considered the essential catalytic feature which "activates" the oxygen for oxidation. This reasoning is based on the spectacular effect of such chemically inert substances as cyanides on respiration. Cyanide causes almost instantaneous death by combining with the iron of the cytochrome and also with hemoglobin. Inhalation of HCN for only two seconds causes unconsciousness in six seconds and death in sixteen seconds. Other substances, as carbon monoxide, which combine readily with these respiratory carriers, have a similarly fatal effect. According to Warburg's old theory, cyanide *inactivates* the metal, the activator of the oxygen for oxidation.

Wieland¹⁴, on the other hand, believed that the essential process is not oxygen activation but hydrogen activation by catalysts called dehydrogenases¹⁵, and that the essential feature of oxidation is loss of hydrogen from the metabolite molecule, the oxygen acting as a relatively passive H acceptor. The carbon serves as the framework for the hydrogen. The essential overall reaction in biologic oxidation is accordingly

Szent-Györgyi²⁶ believes that there is no contradiction between Wieland's and Warburg's theories, and that both O and H are activated.

⁶⁹ Cf. Theorell, H., *Biochem. Z.*, **298**, 242 (1938).

⁷⁰ Warburg, O., *Science*, **61**, 575 (1925); **68**, 437 (1928); *Bull. Johns Hopkins Hospital*, **46**, 341 (1930).

Hemoglobin and cytochrome have many similarities: both have the same concentration of iron, both are quickly poisoned by cyanides, sulfides, and carbon monoxide. The difference between the two is that the iron atom changes valence ($\text{Fe}^{++} \rightleftharpoons \text{Fe}^{+++}$) in cytochrome but not in hemoglobin; hence the use of the term "oxidation" for cytochrome and "oxygenation" for hemoglobin. The molecular weight of cytochrome is of the order of 16,500 (assuming 1 Fe per mol of cytochrome), the weight formerly given for hemoglobin. It is now thought that the molecular weight of hemoglobin is about 68,000.

In view of the importance of iron in oxygenation and oxidation, it is evident that iron deficiency leads to serious metabolic disorders, structurally evidenced by *hypochromic* anemia (reduced hemoglobin formation). Like many other catalysts, however, iron is used over and over in the body. Therefore, it is only during growth, gestation, or in blood loss, in diarrhea, and intestinal disease, that considerable dietary iron is needed⁷¹. The dietary utilization of iron has been investigated⁷⁷ most spectacularly with the radioactive isotope Fe^{59} .

It is generally known that *iodine*⁷² is the important inorganic element in thyroxine, a powerful oxidation accelerating hormone (Ch. 7).

There is no doubt that *copper* catalyzes iron utilization for hemoglobin formation⁷³ and that many oxidase enzymes (such as ascorbic acid oxidase, polyphenyl oxidase, cytochrome oxidase, catechol oxidase, tyrosinase, and laccase) contain copper, or are copper-protein oxidases⁷⁴.

Cobalt appears to be an essential trace element in the utilization of iron in sheep and cattle⁷⁵ but, apparently, not in rats.

*Calcium*⁷⁶, likewise, has a stimulating effect on some oxidases, as on succinic oxidase activity (bound up with cytochrome).

Just as hemoglobin and cytochrome contain iron,⁷⁷ so carbonic anhydrase (associated with the equilibrium between carbonic acid and carbon dioxide in their transportation by the blood) contains zinc. This was discovered by Keilin and Mann⁷⁸ and substantiated and extended by Hove *et al.*,⁷⁹ who previously demonstrated that zinc is a dietary essential⁸⁰.

Many other trace elements, such as Al, Be, B, Cr, Si, Sr, Sn, Tl, and Ni, are present in animal tissues⁸¹, but their function, if any, is not understood. Thus

vanadium⁸² is regularly found in egg yolk and some tissues, but its function is not known. Bernheim⁸³, however, reported that vanadium stimulates oxidation of phospholipins in the presence of liver. Molybdenum may have some nutritional function⁸⁴.

Some trace elements are important in food, especially in dairy technology⁸⁵ (Sect. 6.3). Thus, tallowness of sweetened condensed milk is attributed to catalytic oxidations by contact with copper and/or iron. Tallowy, oily, and fishy flavors of butter and ice cream are also attributed to such oxidations of the fats or phospholipids catalyzed by contact with copper and/or iron. Ice cream containing strawberries and related plant materials may develop off-flavors due to the catalytic oxidative action of the plant enzymes on the butterfat or on its phospholipids. The presence of iron (ferrous) in milk may destroy enough vitamin A to cause "salt ophthalmia" in animals fed FeSO_4 with their milk⁸⁶. The low concentration of iron and copper in milk may be "explained" by the fact that their presence would be destructive to some vitamins.

Minerals have, of course, other functions, physicochemical⁸⁷ and structural⁸⁸. Thus the skeleton contains about 85 per cent calcium phosphate, and in fact the total body ash contains about 75 per cent calcium phosphate. About 70 per cent of the body's phosphorus is in the skeleton. The phosphate is thus an extremely important structural as well as catalytic group.

6.4.3: Vitamins in biologic oxidations with special reference to the relation between vitamin B and bios. The vitamins are usually divided into fat-soluble and water-soluble categories⁸⁹.

Little is known about the catalytic significance in oxidoreductions of the fat-soluble vitamins. They are not universally distributed or needed. Cockroaches⁹⁰, for example, need no vitamin A; goats⁹¹ need no vitamin E; yeasts need no vitamins A, E, D, or K.

The functions of the fat-soluble vitamins are rather more specialized than general oxidoreduction. Thus *vitamin A* is the prosthetic group of a very

Vitamin A is apparently not a basic or general biocatalyst; nevertheless in some species its deficiency leads to widespread and grave symptoms. The vitamin A deficiency symptoms in humans are generally known. Vitamin A deficiency in growing cattle leads to constriction of the optic foramen with consequent optic nerve constriction and blindness; syncope likely produced by increased intracranial pressure; papillary edema and nyctalopia; bleaching of the tapetum lucidum of the retina, but not keratitis⁹⁴; degeneration of germinal epithelium of the testes and absence of spermatozoa, and changes in the pituitary (T. S. Sutton); enteritis, kidney and liver lesions, and diarrhea⁹⁵.

Vitamin E (α -tocopherol⁹⁶) may be a respiratory enzyme⁹⁷, but the most striking effects⁹⁸, in case of deficiency, are on the pituitary⁹⁹ and reproduction in general, leading to resorptive sterility and degeneration of the germinal epithelium in rats^{99, 100}, muscular dystrophy and paralysis in rats, guinea pigs and rabbits¹⁰¹ and encephalomalacia in chicks¹⁰² (Ch. 20).

Vitamin K, a quinoid¹⁰³, such as 2-methyl-1,4-naphthoquinone, may be an oxidation catalyst¹⁰⁴, but it is known only as being necessary for prothrombin formation. Prothrombin is, in fact, the proenzyme of thrombin, which converts fibrinogen to fibrin in blood clotting.

Vitamin D (irradiated ergosterol or 7-dehydrocholesterol¹⁰⁵) is known for its catalysis of absorption of calcium and phosphates from the intestinal tracts, bone formation, and prevention and cure of rickets¹⁰⁶.

On the contrary, most of the water-soluble vitamins of the vitamin B or the bios type appear to be almost universally distributed and involved in basic oxidoreductions.

The story of the development of our knowledge of the interrelation between

vitamin B and bios¹⁰⁷ is fascinating. About 1860 Pasteur¹⁰⁸ observed that yeast requires some factor for growth and fermentation which Wildier¹⁰⁹, in 1901, called *bios*. It is now known that bios is not a factor, but a family containing perhaps a dozen members, designated "growth factors". The important development emerged that the yeast "growth factors" are identical with a dozen-odd vitamins which make up what is now called the vitamin B complex. Nine of these factors have been obtained in crystalline form.

The modern study of the B vitamins may be said to have begun¹¹⁰ with the antiberiberi or antipolyneuritis factor, now called thiamine or vitamin B₁. About 1897 Eijkmann¹¹¹ observed that beriberi results from the lack of a substance present in rice polishings. In 1911 Funk¹¹² prepared the beriberi-curative substance from rice polishings; detecting an amine therein, he named the substance vitamin—a "vital amine". It was a charmed name which outlasted the accessory food substance and growth-factor designations employed by¹¹³ Hopkins and by Osborne and Mendel.

Peters¹¹⁴ observed that thiamine deficiency in the diet results in deficiency of cocarboxylase, the catalyst for splitting CO₂ from pyruvic acid with consequent accumulation of pyruvic acid, associated with the beriberi syndrome.

The function of thiamine is that of a prosthetic group in a respiratory enzyme. But, of course, like other vitamins, it also influences growth rates which are coupled with oxidoreductions; the early assay work for thiamine, as for other vitamins, was conducted by the growth method.

The knowledge of the B vitamins (needed by higher animals) thus paralleled the knowledge of bios or growth factors (needed by yeast and other plants). But it is only recently¹¹⁵ that it has become definitely known that the two, bios and vitamin B, are identical. Yeast, liver, and rapidly growing plants are the best source of the B vitamins.

Note, however, the difference in the synthesizing powers of animals and

¹¹⁵ Williams, R. J.¹⁰⁷

plants. Animals must obtain theirs from external sources, hence, by definition, they are *exogenous catalysts* to animals; yeast and other plants synthesize them, hence, by definition, they are enzymes or hormones, *endogenous catalysts*, to plants.

Many animals, especially ruminants (cattle, sheep), need B vitamins, yet do not need them. They require them for their metabolic processes, and their tissues cannot synthesize them; but their gastrointestinal flora produce them in great abundance. Cattle¹¹⁶ certainly do not need thiamine¹¹⁷ (B₁), riboflavin¹¹⁸ (B₂), niacin¹¹⁹, pantothenic acid¹²⁰, pyridoxine¹²¹ (B₆), ascorbic acid,¹²² and perhaps vitamin K, other than supplied by the rumen flora. Indeed, it is said that cow manure is very rich in the B vitamins; it is certainly the richest known source of biotin¹²³.

Prior to a certain age, when the rumen begins to function, calves apparently do need an external source of the B vitamins, normally obtained from milk¹²⁴.

As previously noted, primate and guinea pig must ingest ascorbic acid with the food—it is a real vitamin, an exogenous catalyst to these species; but other species investigated synthesize ascorbic acid in the body, perhaps in the liver¹²⁵ and elsewhere, in fact, ascorbic acid tends to be destroyed in the intestinal tract of some species, such as cattle¹²⁶. It should be understood, however, that low vitality due to any cause, such as poor nutrition and advanced age, is associated with reduced vitamin C production in animals that normally produce it, in which case ascorbic acid administration is indicated¹²⁷.

All animals must have ascorbic acid, an indispensable hydrogen carrier¹²⁸,

dehydroascorbic acid + 2GSH → ascorbic acid + GSSG
Glutathione is also said to protect ascorbic acid (reduced form) from autoxidation.

Why does not the guinea pig synthesize ascorbic acid? Because, says Szent-Györgyi¹²⁹, the guinea pig was evolved in the tropics, always surrounded by ascorbic acid-rich green herbage; survival did not depend on ascorbic-acid production. Therefore, in the course of evolution this species lost the ability to produce it, or did not have to develop it. The same argument is extended to primates, who cannot produce ascorbic acid: they originated in the tropics.

Only dogs, pigs, and primates were definitely shown to be dependent on dietary nicotinic acid. It appears that rats and chickens can synthesize nicotinic acid,¹³⁰ without the aid of gastrointestinal flora.¹³¹

It thus seems that there are species, and perhaps individual differences in vitamin requirements; one, but not another, for example, develops rickets under the same conditions of vitamin D and calcium supply. The same is true of other vitamins.

Moreover, there are interesting supplementary vitamin and substrate relations. Thus, as is generally known, vitamin D is most effective with a milk diet, which is the reason for fortifying milk with vitamin D. There are similar supplementary relations between vitamins. Thus biotin is practically without effect on yeast growth unless pyridoxine is simultaneously added to the culture medium.¹³² Certain rat aerodynias are more easily cured if both unsaturated fat and pyridoxine are fed than if only one of them is fed.¹³³ Pyridoxine and the essential fatty acids (especially linoleic, arachidonic and linolenic) supplement each other.¹³⁴

Some, but not other, species or individuals may perhaps possess alternate catalysts when the normal one is lacking, or be more sensitively receptive to a given catalyst or to its lack.

Thiamine and riboflavin supplement each other, as indicated by the enormous acceleration of urinary riboflavin loss on decreasing the thiamine intake.¹³⁵

Vitamins have many extremely interesting supplementary, antagonistic, balancing and detoxifying effects.

Thus to cite a few examples, Holmes¹³⁶ reported that ascorbic acid, in doses from 250 to 500 mg per day, detoxifies the excessive production of histamine,

$C_6H_5N_2$, associated with hay fever, thereby relieving this ailment; Carratala¹³⁷ observed a detoxicating action of ascorbic acid in gold therapy; Levine¹³⁸ reported that vitamin C corrects in infants a disorder associated with excess ingestion of tyrosine and phenylalanine; feeding rice bran and yeast extracts tends to inhibit the development of certain types of cancer.¹³⁹ Fat synthesis in the body is dependent on the presence of all three vitamins—riboflavin, pyridoxine, and pantothenic acid¹⁴⁰. The dietary need for biotin varies directly with the consumption of raw egg white (avidin) which binds the biotin, and there is an interesting interrelation between biotin, pimelic acid, and avidin (see below, p. 126). Raw fish has a substance which apparently similarly inactivates thiamine leading to "Chastek paralysis", a thiamine-deficiency syndrome resembling Wernicke's disease in man due to alcoholism.¹⁴¹ The toxic effects of the sulfa drugs are antagonized or neutralized by thiamine and *p*-aminobenzoic acid^{142, 143} (Fig. 6.2). Hyperthyroidism is relieved by vitamins C and A¹⁴⁴. Methionine or choline and homocystine, detoxify pyridine¹⁴⁵, forming harmless methyl pyridinium hydroxide. Riboflavin often exerts a "sparing action" on thiamine¹⁴⁶, and so on. We shall presently note other supplementary relations, such as that of *p*-aminobenzoic acid and inositol; pyridoxine and fatty acid; choline and methionine.

There is a curious structural relation between thiamine (B_1), riboflavin (B_2), pyridoxine (B_6), and nicotinic acid discussed above.

Williams employed the designation thiamine for vitamin B_1 because it contains a thiazole group.

But it also contains a pyrimidine or diazine group

so that the formula of thiamine hydrochloride is

The relative functional importance of the two groups, thiazole and pyrimidine, is discussed by Lipmann.¹⁶⁵

The interesting aspect from the viewpoint of unity in diversity is that riboflavin (vitamin B₂) also has a pyrimidine group. In this case, however, the pyrimidine group is coupled not to a thiazole, but it is a part of isoalloxazine, as indicated by the formula of *d*-riboflavin

A ribityl group, CH₂(CHOH)₃CH₂OH, is attached to position 9; hence the name 6,7-dimethyl-9-*d*-ribityl isoalloxazine.

This substance was apparently first observed by Szent-Györgyi¹⁶⁶ in his studies on biological oxidation-reduction systems (not vitamins). Szent-Györgyi called it *flave* and *cytoflave*.

Nicotinic acid (niacin), contains a closely related ring, not *pyrimidine*, but *pyridine*. Indeed, 3-pyridine-3-carboxylic acid amide

is the active antipellagra factor¹⁶⁷, when combined in the body with phosphoric acid, adenine and pentose (which together constitute cozymases I and II). Nicotinic acid has a —COOH group in place of —CONH₂.

A., *Id.*, **110**, 622 (1938). Elvehjem, C. A., "Relation of nicotinic acid to pellagra," *Physiol. Rev.*, **20**, 249 (1940).

Pyridoxine (B_6) also contains a pyridine ring. Pyridoxine hydrochloride is 1-methyl-2-hydroxy-3-4-dihydroymethyl pyridine hydrochloride

This is an antidermatitis factor for rats¹⁶⁸ and a growth-stimulant for yeast¹⁶⁹, exised tomato roots¹⁷⁰, and so on. Unlike nicotinic acid, however, pyridoxine has not (yet) been shown to be a constituent of an enzyme, but it exists in nature as part of a protein complex, which may be the enzyme.

Pyridoxine deficiency may lead to convulsions¹⁷¹ resembling epileptic fits in rats, pigs, and dogs. It is also needed by chicks. Pyridoxine appears to be a factor in hemoglobin formation and fatty acid utilization.¹⁷²

It appears to be involved in protein metabolism and in the synthesis of fat from protein.¹⁷³

We thus have two pyrimidine vitamins: thiamine (B_1) and riboflavin (B_2); and two pyridine vitamins: nicotinic acid and pyridoxine (B_6).

Coenzymes I and II are pyridine (nicotinic acid) derivatives, composed of one nicotinic acid, two pentoses (ribose), an adenine nucleotide, and two and three phosphoric acids, respectively. Hence the coenzymes I and II may be called di- and tri-phosphopyridine nucleotides, respectively.

The flavoprotein enzymes, such as Warburg's yellow enzyme, are structurally similar to the coenzymes I and II except that they have riboflavin, a pyrimidine group, instead of nicotinic acid, a pyridine group. The yellow enzyme, for example, is therefore diphosphopyrimidine nucleotide, just as cozymase I is diphosphopyridine nucleotide:

	phosphate-ribose-riboflavin	enzyme

There is a striking difference between the amounts of different vitamin requirements in relation to body size. It appears that the need for the universally required vitamins of the vitamin B group, which are definitely participants in oxidations, such as thiamine, vary in proportion to energy metabolism, approximately in proportion to surface area; whereas the specialized vitamins, such as vitamin A, are probably needed in proportion to simple body weight.

When the energy-metabolism level is changed, the need for these oxidation vitamins is probably changed proportionately. This was reported by Mills and by György as regards the influence of change of temperature on thiamine and pyridoxine needs¹⁷⁴, by Drill and Overman as regards the influence of thyroid administration on pantothenic acid needs¹⁷⁵, and by the Pennsylvania Experiment Station¹⁷⁶ as regards the influence of exercise on thiamine need. Fever is known to increase the need for vitamin C.¹⁷⁷

The numerical values for the vitamin requirements of different species and body weights cited in Chapter 20 bear out this statement as far as data are available.

The following are some of the more recently investigated vitamin or bios factors.

Pantothenic acid (name derived by R. J. Williams from the Greek meaning *from everywhere*, since it was found in most diverse living organisms), of which the lactone form is¹⁷⁸ $\text{CH}_2 \cdot \text{C}(\text{CH}_3)_2 \cdot \text{CHOH} \cdot \text{CO}$, and the active form with

β -alanine is $\text{CH}_2\text{OH} \cdot \text{C}(\text{CH}_3)_2 \cdot \text{CHOH} \cdot \text{CO} \cdot \text{NH} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{COOH}$, a component of the "filtrate factor"¹⁷⁹ (chick antidermatitis), is a growth-stimulant for yeast and perhaps for all microorganisms. It is a coenzyme in some fermentation processes.¹⁸⁰

The *vitamin H* of György¹⁸¹ and others was recently found to be identical with coenzyme R of Allison, Hoover, and Burk¹⁸², identical with *biotin*, $\text{C}_{10}\text{H}_{16}\text{O}_3\text{N}_2\text{S}$, a urea-thienyl valeric-acid compound.¹⁸³

Biotin, found in milk, egg yolk, liver, yeast, etc., increases respiratory metabolism in *Rhizobium*¹⁸², fermentative and respiratory metabolism in yeast¹⁸⁴, protects rats¹⁸¹ against the raw egg-white toxic factor¹⁸⁵, avidin¹⁸⁶, and chickens against perosis.¹⁸⁷ The superficial symptoms in the rat are eczematous dermatitis involving eyelids and lips and an ischemic gangrene of the tip of the tail.

A recent sensational observation is that biotin has a procarcinogenic effect on tumor formation induced by feeding the azo dye butter yellow to rats¹⁸⁸ and that riboflavin and related vitamins counteract the carcinogenic properties¹⁸⁹. Like embryonic tissue, tumor tissue is richer in biotin than normal adult tissue^{190,191}. Pimelic acid may be a biotin precursor, and one is an accessory growth factor in the absence of the other¹⁹².

Inositol, a hexahydroxycyclohexane,

widely distributed in biological material in the form of phosphoric ester, ("phytin" in plants, "muscle sugar" in animals) is a member of the bios com-

plex¹⁹³ and is one of the antidermatitis and antialopecia vitamins¹⁹⁴. However, the alopecia also develops in mice even in the presence of inositol if there is pantothenic acid deficiency¹⁹⁵. It appears that mice can synthesize inositol if pantothenic acid is present¹⁹⁶; the synthesis is perhaps accomplished by bacteria in the digestive tract.

Inositol deficiency may lead to the "biotin type" of fatty liver in the rat¹⁹⁷ or, like lipocaic, it appears to prevent the "biotin type" of fatty liver but not the "thiamine type".

There is a curious relation between inositol and *p*-aminobenzoic acid; addition of *p*-aminobenzoic acid often precipitates the inositol-deficiency syndrome, and *vice versa*, causing a graying of hair in black rats similar to the graying due to pantothenic acid deficiency¹⁹⁸.

p-Aminobenzoic acid,

a member of the bios complex¹⁹⁹, was announced by Ansbacher²⁰⁰ to be an "anti-gray hair factor" for black rats fed under certain conditions. It is said that it is not the absolute amount of *p*-aminobenzoic acid that is important in this syndrome, but its ratio to pantothenic acid, which controls the growth of the vitamin-synthesizing powers of the gastrointestinal flora²⁰¹. Sure²⁰² reported that it may be a factor in fertility and lactation in the rat. It affects tyrosinase activity²⁰³.

closely related to acetylcholine, is a component of the phospholipid lecithin,

is often thought of as a vitamin²⁰⁴, sometimes as a bios or growth factor since it is required by some bacteria and as a member of the B-vitamin complex²⁰⁵. However, growing rats can synthesize choline²⁰⁶ (see below). It is mostly known for its catalysis of lipid phosphorylation (formation of phospholipid) and transport and oxidation²⁰⁷. Lack of dietary choline (or lecithin, or certain other methyl-containing groups), however, leads to diverse syndromes, such as perosis in chicks²⁰⁸, impairment of lactation²⁰⁹ (rats), fatty livers^{207,210}, hemorrhagic renal lesions²¹¹, deficient vagus function (inadequate acetylcholine formation)²¹².

The body is apparently able to synthesize choline provided that the diet contains "labile methyl" groups^{213, 214, 215}, such as are present in methionine and betaine. Indeed, it appears that it is not choline that is the important factor but methyl groups in utilizable form for transmethylation (specific transfer of methyl groups as needed) and that the methyl groups of choline, methionine, and betaine are thus transferable.

From the above discussions it appears that choline is a "vitamin" in the special sense that it supplies indispensable methyl groups if the diet is inadequate in methionine (below 0.8 per cent methionine; or if casein is the sole source of protein, less than 30 per cent casein in the diet). Increasing cystine in the diet, or increasing food intake of any kind, increases the choline requirement²¹⁶. High-fat and low-protein diets similarly increase the choline requirements, which if not satisfied may lead to cirrhosis of the liver²¹⁷.

in **heterotrophs**. Anabolism, or biologic synthesis, is necessarily coupled with catabolism, or biologic oxidation, discussed in the preceding sections, and some of the same oxidoreduction catalysts involved in catabolism are also involved in anabolism. This section presents a few examples of biologic synthesis beginning with a brief footnote, by way of reference to the literature, on the assimilation of CO₂-carbon by heterotrophs.

Winogradsky²¹⁸ discovered in 1890 that some soil organisms obtain energy by oxidation of ammonia to nitrites, and nitrites to nitrates, and using this energy for carboxylation, that is, assimilation of carbon from atmospheric CO₂, independently of radiant energy, for building up their tissues (Ch. 2).

The new development is that saprophytic bacteria and certain tissues of warm-blooded animals thought to be able to utilize only complex organic substances (carbohydrates, fats, proteins, and their close derivatives) have been observed to utilize CO₂. These investigations have been greatly aided by the use of isotopes—heavy carbon, C¹³, and radioactive carbon, C¹¹—as tracers.

The literature, adequately reviewed²¹⁹, indicates three paths of investigation. First is the fixation of CO₂ in urea formation by the liver. This was demonstrated by Krebs²²⁰ in 1932, confirmed by Rittenberg²²¹, using C¹³, and Evans²²², using C¹¹.

Second is the utilization of CO₂ in heterotrophic bacteria, discovered by Wood and Werkman²²³ in 1935 and adequately confirmed²²⁴ on propionic acid bacteria.

Third, Evans and Slotin²²⁵ discovered and Wood and Werkman²²⁶ confirmed the utilization of CO₂ by pigeon-liver tissue; the latter showed that the CO₂ carbon appeared in the α-ketoglutaric acid and other acids²²⁷. Wood and Werkman²²⁸ proposed the following equation to represent the assimilation of tagged C into succinic acid (if such occurs), indicating that the carbon is fixed in the carbonyl group adjacent to the methylene.

It appears that CO₂ may also be utilized by intact higher animals. C¹¹O₂ was administered in the form of NaHC¹¹O₃ and the C¹¹ was found in the newly formed liver glycogen²²⁹.

In this connection a note may be in order concerning the photosynthetic assimilation of CO_2 . Photosynthesis appears²³⁰ to occur in two stages, (1) CO_2 fixation and (2) utilization of radiant energy for activating the fixation process. The first step appears to occur (but perhaps not in similar manner) in both autotrophs and heterotrophs but, of course, not the utilization of radiant energy in heterotrophs.

In photosynthesis, H_2O is the H-donor and CO_2 is the H-acceptor. As the potential difference between the two is 1.2 to 1.3 volts²³¹, "the wrong side" by about 56 Cal per equivalent, it follows that at least 56 Cal per equivalent, or about 670 Cal (56×6) per mol hexose, is expended for the formation of hexose. Chlorophyll is perhaps the hydrogen carrier in the dehydrogenation of H_2O .

All the fermentation and oxidation processes, such as:

and so on, are, of course, based on previous syntheses. The study of the synthesis, experimental and theoretic (thermodynamic), is in the initial stage, although there is an immense literature on the subject, for heterotrophs²³² as well as for autotrophs.

It may be appropriate to mention an illustration of the reversal of the decarboxylation catalyzed by vitamin B_1 , or rather by thiamine pyrophosphate or cocarboxylase. The decarboxylation reaction cited was

Now it is believed that thiamine pyrophosphate similarly catalyzes the reverse process in heterotrophs, namely carboxylation²³²⁻²³⁴. The process is assumed to be associated with various theoretical "cycles" sponsored by different investigators as, for example, the "citric acid cycle"²³⁵ or the "succinic acid cycle"²³⁶, all beginning with a carboxylation reaction, usually carboxylation of pyruvic acid, under the influence of various catalysts, of which carboxylase is one.

There is a great deal of discussion in the literature concerning another type of synthesis, namely, that of glycogen from lactic acid.

Though the idea has not generally been accepted²³⁷, Meyerhof²³⁸ suggested that about 25 per cent of the lactic acid formed during intense muscular work

is completely oxidized during the recovery period, and the energy therefrom converts the remaining 75 per cent of the lactic acid to glucose or glycogen. The synthesis of glucose from lactic acid in muscle, and especially in the liver, was demonstrated long ago²³⁹. As in the glycolysis of glucose to lactic acid so in the reverse process, the first stage is phosphorylation, and the first product is phosphopyruvic acid formed from lactic acid²⁴⁰.

In addition to Meyerhof's theory²⁴¹ of the synthesis of glucose from lactic acid, others have been suggested²⁴². Tentative data and theories are also available²⁴³ on the formation of triose from phosphoglyceric acid, glucose from triose, and glycogen from glucose. Similarly, tentative data and theories are available for reductive amination processes, that is, synthesis of amino acids from intermediate carbohydrate-metabolism products²⁴⁴, as for the oxidative deamination processes (Sect. 20.7).

The reaction

is reversible²⁴⁵. Thus glycolysis (in the presence of ammonia) may thus yield alanine instead of lactic acid.

6.6: Summary and appendix. A brief discussion is presented of some of the mechanisms of biologic oxidation or dissimilation or catabolism, and of synthesis or assimilation or anabolism. Some of the water-soluble vitamin are involved in all biologic oxidation, ranging from bacteria to man; the fat-soluble vitamins, on the other hand, appear to be involved in special processes found only in higher animals.

Biologic oxidation is a stepwise process involving many intermediate steps and catalysts, as indicated diagrammatically:

phosphorylation catalysts and donors, such as phosphorylases and adenylic pyrophosphate	pyridinoprotein enzymes flavoprotein enzymes iron-porphyrin enzymes cytochromes cytochromes oxidases, etc., involving vitamins and inorganic groups.	carboxylase and cocarboxylase (vitamin B ₁)
---	---	---

The oxidation consists in elaborate, stepwise, transfer of electrons from the electron donors (substrates) to electron acceptors. The ultimate electron

acceptor in aerobic oxidation is atmospheric oxygen; but in fermentation the acceptor may be formed by the electron donor. A central feature of biologic oxidations is that they are coupled with phosphorylation of the carbonyl groups of the substrate, forming various intermediate phosphate esters.

The following is a list of definitions of the vitamins, minerals, and their associated enzymes. The nutritional aspects of vitamins are discussed in Sections 20.5 and 20.6. See Section 7.8.3 for vitamins and hormones in green plants.

I. B vitamins or bios

1. *Thiamine*, vitamin B₁, antineuritic factor: Eijkman 1893, Funk 1911; crystallized by Jansen & Donath, 1926; C₁₂H₁₇ON₄SCl·HCl (Windaus 1931); a thiazole pyrimidine synthesized by Williams, 1936. It exists in the organism in the free form and as component of carboxylase and of cocarboxylase, a thiamine phosphoric ester (Lohmann and Schuster 1937) catalyzing the decarboxylation of pyruvic acid to acetaldehyde and CO₂ and also, carboxylation in the assimilation of CO₂.
2. *Riboflavin*, *lactoflavin*, vitamin B₂: C₁₇H₂O₄N₄O₆, (Kuhn, et al., 1934); an isoalloxazine (Kuhn & Karrer, 1935), containing a pyrimidine ring. Exists as: (A) free riboflavin; (B) "coenzyme": (a) riboflavin-phosphate mono-nucleotide and (b) riboflavin-adenine-dinucleotide; (C) flavoprotein, which is the "coenzyme" in combination with protein. The free riboflavin is available to animals after phosphorylation. Milk contains the riboflavin mostly in the free and coenzyme forms, where it is called lactoflavin (Laki, 1933) and cytoflavine (Banga and Szent-Györgyi, 1932). But egg, liver, yeast, young vegetation, and all rapidly-growing things are rich in it. The blue *B. pyocyaneus* color, which disappears on removal of air, indicates its reversible hydrogen-donating and accepting (carrier) functions. The riboflavin protein enzymes (hydrogen carriers) are exemplified by the "yellow enzyme" of Warburg and Christian, 1932, a mononucleotide; *d*-amino oxidase and diamine oxidase, dinucleotides; the diphorases, dinucleotides; xanthin oxidase, glucose oxidase, cytochrome-c reductase, mononucleotides, and so on.

While the most conspicuous symptom of thiamine deficiency is nerve disease, that of riboflavin deficiency is skin (including eye, hair—alopecia—, etc.) disease, resembling vitamin A deficiency, leading to visual disturbance (often cataract, corneal opacity or keratitis) pellagra-like dermatitis, cheilosis (see under pyridoxine), scaly desquamation, inflammation of tongue, and so on. However, riboflavin deficiency also results in serious neuropathologic conditions²⁴⁶.

3. *Nicotinic acid*, *nicotinamide*, niacin, PP (pellagra-preventing), G²⁴⁷, C₆H₅O₂N or C₆H₄ON₂, pyridine-3-carboxylic acid: found in rice polishings by Funk (1912), who also thought that pellagra is a nutritional disease, but he did not connect nicotinic acid deficiency with pellagra. This was done a quarter century later (1937–8) by Elvehjem, et al., for blacktongue in dogs and by Lepkowsky, Jukes, et al., on man.

This vitamin exists in the form of two coenzymes (or cofactors, or cozymases, or codehydrogenases, or coreductases), coenzyme I, diphosphopyridine nucleotide, and coenzyme II, triphosphopyridine nucleotide (Warburg and Christian, 1935). As for riboflavin coenzymes, the nicotinamide enzymes may exist in combination with proteins; and as riboflavin enzymes, the nicotinamide enzymes are hydrogen carriers. In fact the hydrogen or electron is passed from the pyridine enzymes to

²⁴⁶ Shaw, J. H., and Phillips, P. H., *J. Nut.*, **22**, 345 (1941).

²⁴⁷ G, after J. Goldberger, the pioneer investigator. See *Public Health Reports*, **30**, 3117 (1915), and many papers thereafter.

the flavin enzymes. Coenzyme I catalyzes the equilibria, lactate \rightleftharpoons pyruvate, B-hydroxybutyrate \rightleftharpoons acetoacetate, alcohol \rightleftharpoons acetaldehyde, and so on; coenzyme II catalyzes the equilibria, citrate \rightleftharpoons α -keto-glutarate, glucose-6-phosphate \rightleftharpoons 6-phospho-gluconate, and so on.

The clinical symptoms are typical skin afflictions, mental confusion, and diarrhea.

4. *Pyridoxine*, vitamin B₆, C₈H₁₁O₃N (Kuhn, 1938): a pyridine compound (1-methyl-2-hydroxy-3-4-dihydroxymethyl pyridine, Kuhn and others, 1939), apparently exists in the body in the form of pyridoxine-protein. The symptoms of pyridoxine deficiency in the rat, is a dermatitis or acrodynia, similar to pellagra in man or blacktongue in dogs; also hypochromic anemia. Goldberger and Lillie, 1926, designated rat acrodynia factor; Chick, 1930, called it the Y factor; Richardson and Hogan, 1936, called it vitamin H; Lepkowsky, 1936, called it the I factor; György, 1939, called it pyridoxine and vitamin B₆, which name has been generally adopted. Pyridoxine appears to cure "cheilosis", formerly believed to be due to ariboflavinosis. Pyridoxine and nicotinic acid appear to be related functionally as well as structurally.

Both thiamine and pyridoxine are involved in the synthesis of fat from protein²⁴⁸.

5. *Pantothenic acid*, C₉H₁₇O₅N, [the commercially available salt is Ca(C₉H₁₆NO₅)₂] a dimethyl butyryl amide (R. J. Williams *et al.*, 1939): an antidermatitis factor for chicks (many workers, especially Jukes, 1939, and Elvehjem *et al.*, 1939), growth stimulator, etc.
6. *Biotin*, coenzyme R, anti-avidin, or anti-egg-white injury factor, antiperosis factor, vitamin H of György, isolated and named by Kögl, 1935, C₁₀H₁₆O₃N₂S, a urea-thienyl valeric acid compound (du Vigneaud, György, *et al.*, 1940-2): Biotin deficiency in rats is recognized by the "spectacle eye" syndrome, and dermatitis in chicks, and other lesions.
7. *Inositol*, C₆H₁₂O₆, hexahydroxycyclohexane (Eastcott, 1928), a carbohydrate derivative. It is an antialopecia factor (Woolley, 1940), very widely distributed. It is a lipotropic factor (Gavin and McHenry, 1941).
8. *p-Amino benzoic acid*, C₇H₇O₂N, antiachromatricia factor for black rats (Ansbacher, 1941): very widely distributed in biologic material.
9. *Choline*, lipotropic factor (Best *et al.*, 1932): the methyl group is its essential component. Like betaine, choline has 3 methyl groups. The amino acid methionine, CH₃-S-(CH₂)₂-CHNH₂-COOH, also has a methyl group; hence these three substances can be substituted for each other. Deficiency of the methyl grouping leads to "fatty livers", cirrhosis of the liver, hemorrhagic kidney degeneration, disturbance of lactation and growth, and paralysis of the suckling young.
10. Many more members are suspected in the B-complex family, and some have been proved to be present; but the chemical constitution of these has not yet been worked out. To avoid confusion, only three of the best known of these factors are cited. First is vitamin B₉, or the chick antianemia vitamin discovered and crystallized from aqueous liver extract by Hogan and associates²⁴⁹. It is a dietary essential for at least the chick, pigeon, and guinea pig. Vitamin B₉ may be identical with a spinach concentrate prepared by Williams *et al.* and designated folic acid²⁵⁰; it may

be identical with the norit eluate factor of Snell and associates, who called it *Lactobacillus casei* growth factor²⁵¹; it may be related to the "extrinsic factor" of Minot *et al.*²⁵². A second of these unknowns on which there is an interesting literature is the "grass-juice factor"²⁵³, richly present in young grass, good silage, and in milk of cows fed on young grass or good silage. There was considerable interest in an "anti-gray hair" vitamin first reported on by Morgan²⁵⁴ prepared from the "filtrate factors". The "filtrate factor" referred to above is found in water solutions of extracts of liver, yeast, rice-bran, and related substances, after removing thiamine, riboflavin, and pyridoxine by shaking with fuller's earth. The "filtrate factor" residue contains, among others, pantothenic acid and *p*-aminobenzoic acid, which some claim to be anti-gray hair factors. It appears, however, that premature graying of hair may reflect any one of many metabolic disturbances due to the lack of any one of the several nutritional factors. To quote from Adolphus Greeley's account of his 1881 Arctic expedition: "When rescued at Cape Sabine my hair was entirely white, probably due to semi-starvation, and darkened again within a year". The mechanism of graying is a fascinating problem at present under investigation.

- II. **Ascorbic acid**, vitamin C, anti-scorbutic factor, is water-soluble, but it is not considered to be a member of the B-vitamin or bios family. Like higher animals, some microorganisms synthesize it, others obtain it from the substrate, and still others apparently do not need it at all.

The conspicuous symptom of vitamin C deficiency, in susceptible animals, is scurvy, a disease long known. Its scientific study on the guinea pig as well as on man is associated mostly with Holst and Frölich (1907), with Zilva, who obtained vitamin C in pure form and investigated its properties (1918), and with Szent-Györgyi (1928) and King (1932), who recognized the identity of vitamin C with an oxidation-reduction biocatalyst. Its chemical configuration was determined in 1933 by several groups of workers. Its empirical formula is $C_6H_8O_6$ and its structural formula is variously written as

While most animals (primates and guinea pigs excepted) synthesize their own ascorbic acid, its rate of synthesis declines with decline of general vitality due to poor diet and perhaps advancing age, so that old cattle, for example, benefit by ascorbic acid injection. It is a powerful general detoxifying agent, and its administration is helpful during exposure to toxins, disease, and related stresses.

Citrin, vitamin P (P stands for permeability and for paprika from which an extract was made) was reported by Szent-Györgyi²⁵⁵ as occurring together with vitamin C

and having similar functions. It appears to be a component of a hydrogen transport, or of oxidoreduction system²⁴⁶.

III. Fat-soluble vitamins

1. *Vitamin A*, antixerophthalmic factor, is a derivative of carotene, $C_{40}H_{56}$ (Willstätter, 1906). The constitution of vitamin A was established by Karrer, Kuhn and Zechmeister in 1931, and Kuhn, Holmes, and others synthesized it in 1937.

The provitamin-A nature of carotene and related substance was demonstrated nutritionally by Steenbock, 1919. The relation between the two is now believed to be:

However, the physiologic efficiency of this conversion is perhaps below 50 per cent, depending on species and other conditions.

The empirical formula of vitamin A is $C_{20}H_{30}O$. The structural formula of vitamin A (half molecule of B-carotene) is:

Karrer received the 1937 Nobel Prize in chemistry for this elucidation.

Vitamin A deficiency leads to many disorders, of which visual and structural disturbances of the eye and inflammation and injury of epithelial tissues are the most conspicuous.

2. *Vitamin D*, antirachitic factor, was recognized to be distinct from vitamin A by Mellanby and by McCollum (1919-22). Of ten-odd D vitamins, only two are practically important, namely D_3 ($C_{27}H_{44}O$), a 7-dehydrocholesterol activated by ultraviolet light, and stored in the liver and skin; and D_2 ($C_{28}H_{44}O$), similarly activated (plant) ergosterol, known as calciferol and viosterol. The activation of ergosterol and cholesterol by ultraviolet light was demonstrated simultaneously by Steenbock and by Hess (1925). This, of course, elucidates the old observation concerning the beneficial effect of light on rickets. Vitamin D is produced not by the organism, but by the action of light on the cholesterol or ergosterol, which are the provitamins, as carotene is of vitamin A.

Windaus isolated, analyzed, and synthesized 7-dehydrocholesterol from cholesterol (1932-5).

The most characteristic syndrome of vitamin D deficiency is softening of the bones, with resulting bow legs, knock knees, pigeon breast, skull-shape abnormalities, and so on. This condition of bone softness in the young is called rickets, and in the old osteomalacia.

3. *Vitamin E*, α -tocopherol, $C_{29}H_{50}O_2$, is mainly known for its effects on reproduction, perhaps by way of the pituitary. Hence the designation for the compounds having this action, as tocopherol, from the Greek for childbearing. The outstanding defi-

²⁴⁶ Wanra, C. A., and Webb, L. J., *Science*, **96**, 302 (1942).

ciency symptoms in the male rat is degeneration of the germinal cells of the testes and, therefore, interference with spermatogenesis; in the female rat, interference with placental function, leading to death and resorption of the embryo (Mattill and Conklin, 1920; Evans and Bishop, 1922), hence the designation "resorptive sterility". Many other symptoms have been reported, especially muscular dystrophy (Evans and Burr, 1928; Goettsch and Pappenheimer, 1930) in rats, rabbits and guinea pigs and encephalomalacia and exudative diathesis in chicks. Evans and Burr (1922) recognized the presence of this vitamin (which they called X). Goats do not need vitamin E. Fernholz worked out its chemical configuration (1937), and Karrer and several other groups synthesized it (1938).

4. **Vitamin K**, an antihemorrhagic factor by virtue of the fact that it is the proenzyme of prothrombin which catalyzes the formation of fibrin (in blood clotting) from fibrinogen. Hence, deficiency of vitamin K (often due to obstructive jaundice, biliary fistula, sprue, colitis, liver diseases, etc.) is a frequent cause of intestinal bleeding. The presence of such antihemorrhagic factor was discovered by Dam (1930-4). Doisy *et al.* isolated and synthesized it, as did others (Fieser, Almquist, Ansbacher and Fernholz). There are several vitamin K substances of which K_1 ($C_{31}H_{46}O_2$), a 2-methyl-3-phytyl-1,4-naphthaquinone, and K_2 ($C_{41}H_{56}O_2$), a 2-methyl-3-difornesyl-1,4-naphthaquinone, are the best known.
5. **Fatty acids**²⁵⁷. The essential (unsaturated) fatty acids, formerly designated as "vitamin F", function primarily as "building stones", like methionine, previously discussed. Their deficiency produces certain effects similar to vitamin deficiency.

The three major essential fatty acids are:

Exclusion of these fatty acids leads, in the rat, to (1) scaly skin and caudal necrosis; (2) growth retardation; (3) kidney lesions; (4) poor reproductive performance; (5) high water consumption and high R.Q. The kidney lesions are the most reliable deficiency symptoms. Usually the higher the fat consumption the higher the need for the unsaturated acids, as unsaturated fatty acids (linoleic acid) are synthesized to some extent from carbohydrate. Certain eczemas in humans are said to be associated with unsaturated fatty acid deficiency²⁵⁸.

It was previously noted¹³³ (Sect. 6.4) that fat has a sparing action on pyridoxine and perhaps on several other vitamins. Corn oil is most effective followed by linseed oil, but not cod liver oil. Corn oil (and presumably others rich in unsaturated acids) is lipotropic, reducing liver fat²⁵⁷.

IV. Mineral groups in oxidoreductions

The *phosphate group* occupies a central position in catabolic and anabolic processes. Many reactions formerly attributed to or explained by hydrolysis are currently elucidated more rationally (thermodynamically) by phosphorylation. The phosphate group is also a component of many enzymes, as of carboxylase, which is a diphosphothiamine-magnesium protein.

Iron is a component of many hemin catalysts, such as of hemoglobin, cytochrome, catalase.

The *manganese* ion activates many reactions, anabolic and catabolic. The Mg, Mn and Co ions may be interchangeable in some processes.

²⁵⁷ Burr, G. O., *Federation Proceedings*, **1**, 224 (1942).

²⁵⁸ Hansen, A. E., *Am. J. Dis. Child.*, **53**, 933 (1937).

Magnesium is a component of chlorophyll (as iron is of hemoglobin) and of some oxidation catalysts, as of carboxylase (see under phosphate).

Zinc is a constituent of carbonic anhydrase.

Copper catalyzes iron utilization for hemoglobin, and it is a component of many oxidases (polyphenol oxidase, monophenol oxidase, laccase, ascorbic acid oxidase) also of hemocyanin, an analogue of hemoglobin in arthropod and mollusk blood.

Cobalt may serve some similar purpose in ruminants.

Calcium appears to be involved in some oxidase activities.

Vanadium may be involved in phospholipin oxidation.

Nitrogen is, of course, a constituent of thiamine, riboflavin, nicotinamide, pyridoxine, biotin, pantothenic acid, choline, as well as of the hemins (hemoglobin, chlorophyll, cytochromes, etc.).

Sulfur is a constituent of thiamine, biotin, and glutathione*.

In addition to the oxidoreduction processes, many inorganic groups are involved in other types of catalysis, in such physicochemical functions as osmotic pressure, and for structural purposes.

V. General definitions

Oxidation and reduction: loss and gain of electrons or loss and gain of protons. It is generally accepted that biologic oxidoreductions are stepwise processes; by enzymatic electron-transfer systems, the *ultimate* electron (and hydrogen) acceptor in *aerobic* oxidation is atmospheric oxygen, forming H_2O ; in *anaerobic* oxidation (fermentation, glycolysis, internal oxidoreduction) the electron acceptor is formed by the electron donor. The metabolites undergoing oxidation are the electron (and hydrogen) donors. The conspicuous catalysts in anaerobic oxidation are pyridine and thiazole enzymes; in aerobic oxidation, also alloxazine and hemin catalysts.

Oxygen debt: anaerobic oxidation in higher animals during intense muscular work when the oxygen supply is inadequate, and intermediate metabolic products accumulate. Recovery occurs when the oxygen supply becomes adequate, and the intermediate products are oxidized.

Oxidation-reduction potential: the electric potential of an element in contact with a solution of its ions at unit activity, referred to that of hydrogen (under standard conditions) as zero.

Oxidation-reduction indicator: a substance existing in oxidized and reduced form and changing color with change in the O-R potential.

Phosphorylation: combination of metabolite with phosphate, under the influence of certain catalysts (see glycolysis), especially adenylyl pyrophosphate, which is the phosphate "carrier". Adenylyl pyrophosphate is composed of one adenylic acid, and two phosphate groups which are "donated" to the metabolite, thus:

Adenylyc acid is involved in alcohol formation from hexose diphosphate, thus:

* Glutathione is a tripeptide consisting of glutamic acid, glycine, and cysteine ($CH_2SH \cdot CHNH_2 \cdot COOH$). Sulfhydryl is the SH in the cysteinyl group. There is an immense literature on the function of glutathione, which may be summarized, from the oxidoreduction viewpoint, by the equation:

Two molecules of $-SH$ (written GSH) are oxidized to one of $-S-S-$ (written GSSG). This is reversible: glutathione reduces ascorbic acid (after oxidation by ascorbic oxidase), thus serving as an electron carrier.

Most electron donors (metabolites) must be phosphorylated as the preliminary step; for phosphorylation and oxidation are indeed *coupled* reactions. A possible example of phosphorylation (Kalekar), forming phosphate-ester bonds, the source of anaerobic energy (Lipmann):

Glycolysis: conversion of carbohydrate to lactate by a series of catalysts, as phosphorylase, phosphatase, aldolase, enolase, dehydrogenase, adenylyl pyrophosphate, Mg^{++} , Mn^{++} , and others. This, as other intermediary processes, may be blocked (Lundsgaard, Krebs) in any of its stages by various "poisons", such as iodoacetate, fluoride, heavy metal, and by certain enzymes as by amylase [Case and McCullagh, *Biochem. J.*, **22**, 1060 (1928); Ronzoni, *Proc. Soc. Exp. Biol. Med.*, **25**, 178 (1928-8)].

Glycogenolysis: conversion of glycogen to glucose; **glycogenesis:** conversion of glucose to glycogen.

Gluconeogenesis: formation of glucose from protein or fat.

Oxidase: enzyme which "activates" oxygen (Warburg).

Dehydrogenase: enzyme which "activates" hydrogen (Wieland-Thunberg).

Carrier: "accepts" hydrogen and is thereby reduced, and then "donates" it to another acceptor and is thereby oxidized. "Carriers" are thus reversibly reduced and oxidized.

Dehydrogenation: is the catalytic transfer of hydrogen (by a "carrier" enzyme).

Example: Methylene blue is reversibly reduced (to colorless) by hydrogen and oxidized (to blue) by oxygen, thus transferring H from donator (metabolite) to oxygen (Thunberg).

Proenzyme, prosthetic group: a precursor of an enzyme, formed near the place of the enzyme action; the active part of an enzyme. Thiamine may be considered as proenzyme or prosthetic group of cocarboxylase (diphosphothiamin protein); nicotinic acid of coenzyme I (diphosphopyridine nucleotide or simply pyridine protein); riboflavin of yellow enzyme (flavin-adenine-nucleotide); carotene of vitamin A; vitamin A of visual protein; vitamin K of prothrombin; cholesterol and ergosterol of vitamin D; iron of iron protoporphyrin or hemin, as of hemoglobin and cytochrome; copper of hemocyanin and of certain oxidases. Similarly iodine may be considered as a prosthetic group of thyroxine, and thyroxine a prosthetic group of thyroglobulin.

Metabolism: the sum total of the chemical changes in the body, including the building up (anabolic, assimilation) and the breaking down (catabolism, dissimilation) processes.

Vitamin applications (Ch. 20): (1) understanding biologic oxidoreduction mechanisms; (2) effect on more complete utilization of feed or food for productive purposes; (3) "detoxifying effects" of some of the water-soluble vitamins under certain conditions on, for example, gold, lead, sulfa drugs, alcohol, thyroxine, some bacterial

toxins, pyruvic, lactic, and acetoacetic acids, histamine (as in hay fever). It is probable that some cortical-adrenal hormones have similar effects. Unlike thyroxine, excess intake of the water-soluble oxidation-reduction vitamins is apparently harmless²⁵⁹, as it is easily excreted through the kidney and sweat glands. Less is known about the effects of excessive and vitamins D and A and some other fat-soluble vitamins.

Quantitative estimation of the need for each of the several vitamins and related factors is confused by their sparing, synergistic, supplementary and antagonistic interrelations. For instance²⁶⁰, vitamin E (tocopherols and also tocoquinones) retard oxidation of vitamin A and carotene; hence the amount of vitamin A or carotene needed is reduced by the presence of vitamin E and conversely, deficiency of vitamin E may result in deficiency of vitamin A. Vitamin E is thus said to have a "covitamin A" activity²⁶⁰. Then, too, some nutrients may actually replace others, serving the same nutritional purpose, acting as "isotels"²⁶¹ (iso, the same; telos, purpose). For instance, nicotinamide and nicotinic acid are "isotelic"; they serve the same purpose in nutrition. Pantothenic acid and beta-alanine are "isotelic" in yeast nutrition. Choline and methionine may replace each other in that both furnish methyl groups, and these are also interrelated with pyridoxine, inositol, essential fatty acids and essential amino acids in their lipotropic action²⁶². Thiamine appears to be essential for the production of ascorbic acid in dogs²⁶³ and vitamin A is necessary for the production of ascorbic acid in cattle¹²⁷. Avidin, biotin, and the bacteriostatic substance "lysozone" of Fleming and Allison²⁶⁴ appear to be interrelated²⁶⁵. (Biotin may be the "active" principle of lysozone and the avidin acts as "binder" in the "enzyme" system.)

Chapter 7

Metabolic Catalysts in the Efficiency Complex: Hormones

It is the avowed purpose of scientific thought to reduce the number of mysteries, and its success has been marvelous. *J. H. Robinson.*

7.1: Orientation. As previously explained (Ch. 6) there is no sharp dividing line between vitamins, *i.e.*, *exogenous catalysts* taken with the food, and hormones or enzymes, *i.e.* *endogenous catalysts* produced within the body. Thus, ascorbic acid is an exogenous catalyst—a vitamin—in man, monkey, and guinea pig, and an endogenous catalyst in other species examined, including the chick embryo (thus excluding possible vitamin C production by intestinal flora). Likewise, the rat is independent of dietary biotin, folic acid, nicotinic acid, and vitamin K which some other species must obtain from food¹.

Clearly, only such substances can be vitamins as are not digested during their passage through the digestive tract and are composed of sufficiently small molecules to be readily absorbed from the digestive tract into the blood. The hormones, on the other hand, need not be so stable nor the molecules so small. The body may have evolved mechanisms for producing internally such catalysts as could not pass through the digestive tract, such as insulin, or which could not reliably be obtained from food, as can ascorbic acid in temperate climate (Ch. 6). The peculiarity of some hormones of being destroyed in the digestive tract was not fully appreciated in early investigations. Thus about 1914 Robertson, Professor of Biochemistry at the University of California, formulated an apparently correct theory of anterior-pituitary hormone function in growth², but he attempted to prove it by feeding pituitary. Evans, Professor of Anatomy at the same institution, however, injected the pituitary substance, with the well-known results to be discussed presently.

The endocrine glands are very small bodies (for detailed weights see Ch. 17). Remembering that 1 ounce is about 28.3 grams or 1 gram is 1/28.3 ounce, the pituitary in

¹ "Synthetic diets" which support growth and reproduction in the rat do not permit survival in the monkey or guinea pig even if vitamin C and the other available vitamins are added. Waisman, H. A., Rasmussen, A. F., Jr., Elvehjem, C. A., and Clark, P. J., *J. Nut.*, **26**, 205 (1943).

² Robertson, T. B., "Principles of biochemistry," 1919, and "Biochemical basis of growth and senescence", Philadelphia, 1922. See, however, Robertson, *J. Biol. Chem.*, **24**, 385 (1916).

70-kg animals (weight of an average man or sheep) weighs only about 0.6 g, which is about 0.0008 per cent of the total body weight. Likewise in mature 70-kg animals the thyroids, one on each side of the trachea, weigh about 6.5 g, which is about 0.009 per cent of the body weight; the parathyroids, usually four glands imbedded in the thyroids, weigh together in mature 70-kg animals about 0.2 g; the adrenals or suprarenals, situated above the kidneys, weigh about 8 g; the gonads, ovaries and testes weigh in mature man about 10 and 25 g, respectively.

Most glands produce more than one hormone and some have more than one anatomic part. Thus the adrenals or suprarenals have a medullary (central) part producing adrenaline and a cortical (shell) part producing adrenocortical hormones. The pituitary, or hypophysis, has a posterior lobe producing pituitrin (pitressin and pitossin or oxytocin) and an anterior lobe producing especially gland activators or, as they are called, trophic or tropic hormones, wherewith it controls many other endocrine glands, especially the adrenals, thyroids, and gonads. Thus the anterior pituitary controls the gonads by gonadotropic hormones, or gonadotropins. The gonadotropins stimulate the gonads (ovaries and testes) to produce sex hormones (estrogen, progesterone, androgen). The familiar sex processes are thus controlled directly by the sex hormones and indirectly by the anterior-pituitary gonadotropins.

Hormones are said to differ from vitamins and enzymes by their endocrine-gland origin. But hormones are not always produced by specialized endocrine glands as usually understood. Thus following the early period of gestation, the sex hormone progesterone is produced mostly by the placenta⁴, which is not thought of as an endocrine, rather than by the corpus luteum, the ovarian progesterone-producing endocrine gland. Gonadotropins, normally produced by the pituitary gland, are produced in great quantities by the placenta (chorionic and equine gonadotropins) during gestation⁵. Indeed, the Ascheim-Zondek pregnancy test⁶ is based on the excretion of chorionic gonadotropins in the urine; and these placental or chorionic gonadotropins, like the pituitary gonadotropins, function therapeutically in hypogenitalism, cryptorchidism, and in growth acceleration⁷. It appears that during gestation many pituitary functions are taken over by the placenta⁸. Moreover, nerve endings, not thought of as endocrine glands, liberate such hormones as acetylcholine⁹ and sympathin, and embryonic tissues produce various categories of hormones (organizers, evocators, etc.).

Some hormones, such as thyroxine may be taken by mouth. Some steride (sex) hormones may even be absorbed through skin¹⁰, especially mucous

membrane. Most hormones are, however, proteins of high molecular weight which cannot pass into the body without digestion.

Hormones are also more complex than vitamins in that while many vitamin reactions may occur in test tubes in the absence of living tissue, hormone reactions apparently cannot be dissociated from living cells. This explains the relative abundance of information on the anatomic and physiologic aspects of endocrinology and scarcity of information on the biochemical mechanisms of hormone action. Biochemical progress has thus far been confined to the isolation, identification, estimation, and synthesis of hormones; little is known about the intimate biochemical hormone mechanisms.

The catalytic functions of hormones appear to be similar to those of vitamins. Thus carbohydrate metabolism involves the catalytic participation of thiamine, riboflavin, and nicotinic acid (Ch. 6), and it also involves insulin, anterior pituitary factors, corticosterone, and adrenaline. In some cases there is a known or a guessed functional interrelation between vitamins, hormones, and enzymes, as for example, between adrenaline, glutathione, ascorbic acid, and cytochrome c.

The biologic effectiveness is probably of the same order, 1 to millions or even to billions¹¹, for vitamins and hormones.

There is another interesting relation between vitamins, hormones, and some other substances illustrated in Fig. 7.1. The sex hormones, the D vitamins, adrenal cortex hormones, bile acids, saponins, and some carcinogens are phenanthrene compounds; they contain the cyclopentano-phenanthrene nucleus (cholesterol nucleus). Many differences, such as those between male and female sex hormones, are very slight, differing only in saturation, in a side chain, or even only in the position of a double bond.

In chemical structure vitamin D is similar to sex hormone, and in function it is similar in some respects to parathyroid hormone (regulating calcium metabolism). However, sex hormones also participate in calcium and other forms of metabolism¹².

An inferred analogy between vitamins and hormones relates to what might be called *anti-vitamin* and *anti-hormone* effects of some substances. It is believed that the sulfa drugs (sulfanilamide, sulfapyridine, sulfathiazole, sulfaguanidine, sulfadiazine, sulfamerazine, sulfasuxidine, succinyl-sulfathiazole, etc.) owe their anti-bacterial potency to their structural similarity to an essential bacterial growth factor, as to *p*-aminobenzoic acid¹³ (Fig. 6.2), and thus compete with *p*-aminobenzoic acid for an enzymatic system involved in bacterial growth. There is similar antagonism between sulfapyridine, or

¹¹ Kögl, F., and Tonnies, B., *Z. Physiol. Chem.*, **242**, 43 (1936) (biotin, 1 to 400 billion). Adrenaline is effective in concentrations of 1 to 400 million. The whole human body contains less than 20 mg of thyroxine.

sulfamerazine, and nicotinic acid¹⁴, both containing a pyridine group. The sulfa drugs may thus be viewed as antivitamin. There may be similar drugs inactivating other vitamins, such as pyriethamine inactivating thiamine¹⁵.

¹⁴ West, R., *Proc. Soc. Exp. Biol. Med.*, **46**, 679 (1942). Light, R. F., et al., *J. Nut.*, **24**, 427 (1942). Teply, I. J., Axelrod, A. E., and Elvehjem, C., *J. Pharm.*, **77**, 207 (1943).

It may be cogent to note in this connection that when 2 to 5 per cent sulfur is added to a chicken ration, the vitamin D in the cod liver oil therein is no longer effective¹⁶.

There are similar anti-thyroid drugs¹⁷, thiourea and aniline derivatives, especially 2-thiouracil (NHCSNHCOCH₃), 2-thiobarbituric acid, and so on; *p*-aminobenzoic acid (NH₂C₆H₄COOH), sulfaguanidine, sulfapyridine, sulfathiazole, etc., which inhibit thyroxine production, perhaps because of their structural similarity to the thyroxine precursor tyrosine and because they compete with it for the enzyme system involved in the production of thyroxine from diiodotyrosine.

These facts and theories on the similarity of the sulfa anti-vitamin drugs and anti-thyroid drugs lead to the thought that the hormone-like carcinogens, exogenous and endogenous (as methylcholanthrene, Fig. 7.1) may, perhaps, likewise interfere with the normal action of some cellular enzyme system¹⁸ and thus change a normal cell to a cancer cell. Increasing age is often associated with metabolic abnormalities, especially of the sex and adrenal-steroid hormones, as judged by increasing age incidence in their dysfunction. This may, perhaps, explain the mechanism whereby castration prevents and alleviates prostate cancer¹⁹ and, perhaps, cancer of other genital tissues. Similarly, ovariectomy reduces cancer incidence²⁰, and estrogen injection increases it.²⁰ A spectacular associative feature of prostatic carcinoma is a high concentration of the enzyme acid phosphatase in the blood¹⁸; this declines sharply on castration. Castration perhaps eliminates the production of some atypical sterides associated with aging, which, analogous to the sulfa drugs in relation to *p*-aminobenzoic acid or nicotinic acid, interfere with normal enzyme processes. A similar situation may hold for adrenalectomy, as the adrenal cortex produces many sex-like steroids. The apparent necessity of pituitary presence for genital-cancer induction substantiates this suggestion of the hormone-like nature of some carcinogens, and of their probable competitive interference with normal function.

The carcinogenic effect on liver of feeding the azo dye "butter yellow"²¹ to rats kept

on a riboflavin-low diet was explained by a similar mechanism²². A metabolic product of this dye, such as *p*-aminophenol, probably interferes with normal enzymatic activity, which in turn may be compensated by adding more riboflavin, preferably in the form of yeast and liver.

A curious aspect relating to the yeast-liver *anti*-carcinogenic action of the dye "butter yellow" is that the vitamin biotin (anti-avidin factor) neutralizes the protective effect of the yeast or liver; biotin is *pro*carcinogenic under the given conditions²³. We thus have a fascinatingly complex problem involving interrelations between carcinogens, hormones, vitamins, and enzymes bearing on one of the most puzzling medical and biological problems—cancer.

A spectacular type of cancer is one produced in the breast of some strains of mice that received during suckling a "mammary tumor inciter"²⁴, apparently nucleo-protein in nature. This inciter apparently becomes active only in late life under the influence of estrogen or carcinogenic provokers²⁵. Similar tumor inciters may, of course, be absorbed during uterine life. An enzyme-virus theory of carcinogenesis has been suggested²⁶.

Cancer incidence is a function of (1) tissue susceptibility, (2) level or action frequency of causative factor, and (3) time of influence.

The time element²⁷ is, of course, an important factor in cancer induction. The longer one lives, the greater the provocations; the longer the period of exposure, the greater the probability of a mishap, especially since increasing age is associated with increasing dysfunction, increasing number and amount of atypical metabolic products, especially of sex-hormone origin, and cumulative excitation and trauma by the cyclically acting sex hormones. It has, indeed, been demonstrated²⁸ that heavy repetitive estrogen injection induces genital cancer, especially breast cancer.

While hormones are named by their most spectacular effects, as "sex hormones", all hormones are, in fact, *general metabolic* hormones; they are all involved in the transformation of energy-matter. Thus the thyroid is involved not merely in energy metabolism but in virtually every process in the body, including mineral metabolism, sex activity, growth and development, and so on. The same is true for every hormone; they are all interrelated and exert wide-spread effects. However, the precise influence of a given endocrine depends on the age of the organism and on the scope of interrelation.

Thus the early chick embryo does well enough without endocrines²⁹, but at later ages the endocrines and their hormones become crucial. Likewise, the effect of the pituitary sex hormones (gonadotropins) on sex activity varies with age³⁰. Administration of some hormones, including anterior pituitary, thyroid and sex hormones, may accelerate growth and senescence at the same time³¹.

As regards the scope of interrelation, some important endocrines, such as the gonads, may be removed with much less effect on general metabolism than

Fig. 7.2a—The pituitary or hypophysis, its position and relative size in 175 to 250 pound hogs (for pituitary weights, see Ch. 17). Figs. 7.2a-d courtesy H. D. Elijah and C. W. Turner, Univ. Missouri Agr. Exp. Sta. Res. Bull. 357, 1942.

others, such as thyroid, adrenal, pituitary. The extirpation of the pituitary is particularly serious, throwing out of gear practically all other endocrines and consequently all productive processes.

The pituitary exerts the widest influence by way of its tropic hormones³² (Figs. 7.2 and 7.3). To illustrate, sex activity is controlled by the anterior pituitary (A.P.) gland. The A.P. elaborates, among others, two gonadotropic hormones: (1) F.S.H. (follicle-stimulating hormone), involved in the maturation of egg or sperm, graafian follicles, and secretion of estrogens; (2) L.H. or I.C.S.H. (luteinizing or interstitial cell-stimulating hormone, the two appear

Returning to Fig. 7.1, not only are male (androgen) and female (estrogen) hormones similar in chemical structure but both are excreted in the urine of males and females. Men excrete about 100 and women about 300 I.U. of estrogen (female hormone) per day. Between 4 and 7 years the estrogen excretion in girls is 8 to 10 I.U. a day; between 7 and 11 years, 20 a day, and about 300 a day thereafter. Boys excrete 20 to 30 I.U. estrogen up to about 14 years, then may increase to 100 (rather than 300 as in girls)³⁴.

³⁴ Nathanson, I. T., Towne, I. E., and Aub, J. C., *Endocrinology*, **28**, 85 (1941). Nathanson and Aub, *J. Clin. Endocr.*, **3**, 321 (1943). Talbot, N. B., et al., *Am. J. Dis. Child.*, **65**, 364 (1943). Greulich, W. W., et al., *Monogr. Soc. Res. Child. Develop. Nat. Res. Council*, **7**, Serial 33, No. 3 (1942); *J. Ped.*, **22**, 518 (1943). The pioneer work is by Gallagher, T. F., and Koch, F. C., *J.A.M.A.*, **108**, 586 (1937) (one woman with "adrenal virilism" excreted 480 capon units of androgen a day as contrasted to 13-79 in normal men and 13 to 50 in normal women).

The androgen (17-ketosteroid) excretion is approximately the same, not only in boys and girls but also in mature men and women³⁵. Gonadotropin excretion is about the same in men and women³⁶, in castrated men and post-menopause women³⁷.

It is curious that bulls and stallions excrete very little androgen (male) hormones—far below the amounts excreted by men and women—but stallions excrete enormous amounts of estrogen (female hormone)³⁸. The androgen or estrogen excretion may represent metabolic products rather than direct gonadal secretions.

Gonadectomized animals excrete estrogens and androgens. Where are they produced? The adrenal cortex hormones (Fig. 7.1) are chemically similar to sex hormones and the adrenal cortex may produce sex hormones. This is confirmed by changed excretion of these hormones in various diseases of the adrenals. The adrenal-cortex hormone *adrenosterone* shows properties similar to *androsterone*, the active male sex hormone. The adrenal-cortex hormone desoxycorticosterone (sodium-retaining factor) is structurally related to the female sex hormone progesterone, to 21-hydroxyprogesterone; 17-hydroxyprogesterone exerts a physiologic influence similar to the adrenal cortical hormone corticosterone³⁹.

There is no sharp dividing line between male (androgen) and female (estrogen) hormones structurally (Fig. 7.1) or functionally, as indicated by the stimulating effect of androgens on females, including growth of the uterus and other female sex organs⁴⁰, and of estrogens on males⁴¹ (when administered at certain levels under certain conditions). Indeed, even the general design of male and female sex organs is similar, being homologous (same anatomic origin) and analogous (similar physiologic function). Thus the ovary and testes follow a parallel course of development (Fig. 17.4), and sex cannot be differentiated in the embryo until late in development and sometimes not even in late life⁴².

This lack of dividing line may also be illustrated by sex inversion in all species. To cite the best known example on a familiar farm animal⁴³, a young female fowl assumes male characteristics on removal of its left (functional) ovary. Its right ovary is then virtually transformed to a *functional* testicle.

difference in growth rate and in other features in males and females after both have been gonadectomized⁵³. There are also prenatal growth differences between the sexes, that is, before sex maturity⁵⁴. Is sex determined by the gonad or is the nature of the gonad determined by the sex of the individual?

It appears that the urinary steroids may not be functional hormones but hormonal degradation products. While some hormones, like thyroxine and adrenaline, are known chemical entities, most are known only by their effects. Of the many anterior pituitary hormones, only the lactogenic (M.W. about 25,000) have apparently been obtained in definite purity⁵⁵; and it is not absolutely certain that this hormone, originally called prolactin by Riddle, is the lactation hormone. Indeed, the effect ascribed to a given hormone may represent the effect of hormonal degradation products, or of several hormones, or perhaps of impurities associated with the hormones rather than of the hormones themselves⁵⁶.

There is a pendulum type of oscillation between the pituitary tropic hormones and their controlled endocrines. Thus under condition of stress, the pituitary liberates excessive adrenotropic hormone which induces the adrenal medulla to produce adrenaline. If the the adrenaline production is excessive, it reacts on the pituitary, depressing production of adrenotropic hormones⁵⁷. The periodic sex endocrine activity is an expression of this type of regulation (Sect. 7.2). Similarly, feeding thyroid depresses the production of pituitary thyrotropic hormone and therefore depresses thyroxine production⁵⁸; indeed it atrophies the thyroid. When the blood thyroxine level is reduced, the pituitary again produces thyrotropic hormone and hence thyroxine. Likewise, massive administration of adrenocortical extract depresses cortin production; it atrophies the adrenal cortex⁵⁹.

Finally, as explained in Chapter 10, there is a remarkable homeostatic interrelation between the food supply, endocrines, hormones, appetite and related factors. Thus dietary deficiency in iodine leads to compensatory hypertrophy of the thyroid; dietary deficiency in calcium and vitamin D leads

to compensatory hypertrophy of the parathyroids. The level of endocrine function in turn influences food intake, as illustrated by four-fold intake of calcium following parathyroidectomy, two-fold intake of dietary energy following thyroid-hormone or insulin administration, and so on. Hormones and diet are closely interrelated (Ch. 10). A most dramatic interrelation is the influence of lack of certain vitamins, especially vitamin E in the rat⁶⁰ on pituitary, thus throwing the whole body economy out of gear (Chs. 6 and 20). The interrelations between the hormones and between diet and hormones are closer than most investigators appreciate; hence the apparently contradictory results and claims by different investigators. Any one of an innumerable number of components—hormonal, dietary, or environmental—may become the weak link in the metabolic chain that we call life.

This brings us to the question of whether or not it may be possible to employ hormones for increasing the productive rates and, therefore, the profit on agriculturally productive processes. It is obvious that hormones have two aspects in the efficiency complex. One is illustrated by the extirpation of a gland taking part in a productive process. Thus extirpation of the sex glands reduces the reproductive efficiency to zero; but it does not follow that the converse of this process, namely administration of sex hormones to normal animals, increases the reproductive efficiency. Likewise, removal of the thyroid gland in the young stunts growth and development; yet this does not mean that administration of thyroid hormone to normal young accelerates growth. Similar statements apply to other endocrines. The organismic view point (Ch. 10) leads to the inference that in the struggle for survival in the course of evolution, or even in selection by man, the component parts of the body had to develop so as to function in symphonic harmony of an optimal pattern. Disturbance of this pattern is likely to cause unfavorable after-effects, and therefore reduced efficiency.

However, there are various efficiency aspects, immediate energetic and monetary, and long-range energetic and monetary (Ch. 1). Increase in immediate efficiency is dependent on greater increase in productive rate than in maintenance-cost rate. Increase in long-range efficiency is dependent on absence of unfavorable after-effects sufficiently serious to offset the immediate gain; long-range failure to the *animal* may or may not be associated with failure to the *animal husbandman*. Thus injurious after-effects which are developed in three years will not affect the monetary profit of the animal husbandman if he plans to slaughter the animal within two years. This problem is at present under investigation, and it seems best to study the facts and reserve the judgment.

Under certain conditions hormone administration would definitely be helpful. Thus valuable old animals becoming infertile only because of definitely

diagnosed hypothyroidism may be helped by thyroid administration. The pituitary endocrine action of undernourished animals may be depressed because of the undernourished condition, in which case administration of whole anterior pituitary substance, supplementing a good diet, may be helpful; but it may not be profitable to do so. In brief, we are not in a position to generalize on this problem at this time.

With the above organismic, or overall, outline of the hormone problem in mind, we proceed to consider some details of each of several endocrine systems. The endocrine literature is extremely voluminous and is growing very rapidly. This chapter does not attempt to cover the literature, but cites only a few illustrative examples, especially in their bearing on the efficiency complex. The current literature can be followed most easily with the expertly critical reviews in the *Annual Reviews of Physiology*, *Annual Reviews of Biochemistry*, *Physiological Reviews*, *Advances in Enzymology*, and especially the *Journal of the American Medical Association* which emphasizes endocrinal applications as well as the involved theory. Most original researches are reported in *Endocrinology* and in the *Journal of Clinical Endocrinology*.

The following sections are intended to supplement this broad introductory outline of the hormone field.

7.2: Hormones in reproduction and lactation. There is an enormous literature⁶¹ on the endocrines, hormones, and hormonal mechanisms of reproduction, including lactation.

There are many sex hormones, male and female, but, as already noted, they all contain the cyclo-penteno-phenanthrene or the cholesterol nucleus⁶² having the formula

which may be considered as a derivative of the three 6-carbon ring phenanthrene, to which is fused the fourth 5-carbon ring.

In its unsaturated form the nucleus offers many points of attachment for side groups in various sequences. This nucleus is, therefore, the mother sub-

⁶¹ The standard technical work is "Sex and Internal Secretions," by many authors, edited by Edgar Allen, Baltimore, 1939. The most fascinating popular book is "Hormones in Human Reproduction", by G. W. Corner, Princeton Univ. Press, 1942.

⁶² Cf. Koch, F. C., in Allen⁶¹; Hopkins, F. G., Dodds, E. C., Parkes, A. S., Ruzicka, L., Cook, J. W., Reichstein, T., and Todd, A. R., "Synthetic organic chemistry in biology and medicine", *Nature*, **142**, 524 (1938). Fieser, L. F., "Chemistry of natural products related to phenanthrene", New York, Reinhold Publishing Corp., 1937, and *Am. J. Cancer*, **34**, 37 (1938). Bills, C. E., *Physiol. Rev.*, **15**, 1 (1935); "Quantitative Biology", Vol. 5, 1937.

stance of many compounds, including androgens or male sex hormones (testosterone, androsterone, and dehydrosterone, the last two probably being urinary excretion products of the first); female sex hormones (ovarian follicular hormone variously called estrone, theelin, progynon, menoforment, estradiol, theelol or estriol, equilin, progesterone⁶³); corticosterone⁶⁴ (hormone from adrenal cortex); vitamin D; bile acids; saponins; embryogenic organizers; carcinogens, and so on (Fig. 7.1).

The chemical differences in the various sex hormones are due mostly to differences in substitutions in positions 3, 5, 17 in the above nucleus, and in stereochemical configuration. The difference between estrone and progesterone is that the former has an HO— in position 3, the latter an O= and by some minor differences in positions 10 and 17. The difference between testosterone and progesterone is only in position 17: Progesterone has the CO·CH₃ group, testosterone the H·OH group. The difference between corticosterone and progesterone is that the former, but not the latter, has an OH in position 1 and in position 17; corticosterone has an CO·CH₂OH group, while progesterone, a CO·CH₃ group. Indeed, corticosterone exhibits progesterone-like activity⁶⁵. It is impressive to contrast the unity of basic structure and *ultimate* function, with the diversity in immediate function.

While the natural sex hormones are built about the phenanthrene nucleus, a synthetic estrogen, diethyl stilbestrol (“stilbestrol”), synthesized by Dodds⁶⁶, namely,

which does not contain the phenanthrene ring, is at least twice as potent⁶⁷ an estrogen as the natural estrogen estrone. The formula of stilbestrol may be rearranged to appear like estrone with two incomplected positions. This does not, however, work out with 3-dimensional models.

An enormous literature on stilbestrol has grown up⁶⁸ since the appearance of the paper by Dodds, Goldberg, Lawson and Robinson in 1938. Stilbestrol has remarkable growth-stimulating properties on the uterus of immature rats and on the mammary gland^{69, 70}, and has lactation-initiating properties⁷⁰. Stilbestrol, however, depresses

⁶³ Progesterone appears to be androgenic. Clausen, H. J., *Endocrinology*, **31**, 187 (1942). There is some antagonism between estrogen and progesterone as presently explained.

⁷⁰ Folley, S. J., Watson, H. M. S., and Bottomley, A. C., *J. Physiol.* (May 14, 1940) p. 15 (1 per cent ointment was applied thrice weekly to the udder of a virgin goat. After a 30-day latent period, milk production increased to 1500 cc per day, the lactation curve resembling a normal lactation curve). Lewis, A. A., and Turner, C. W., Paper presented before the Am. Soc. Animal Prod. Nov. 28, 1940, and *Endocrinology*, **31**, 520 (1942). Stilbestrol stimulated rapid growth of the mammary duct system comparable to that caused by natural estrogen. Lactation was induced in goats up to 600 cc.

lactation after it is established⁷¹. The effect of the stilbestrol is assumed to be by way of the pituitary. More recently another synthetic estrogen, octofolin⁷² (a phenyl-ethyl-hexane), less toxic for a given estrogenic effect than stilbestrol has come into use⁷³.

The *chemistry* of the sex hormones thus appears simple in general design. The *physiology* of the sex cycle differs with the species: some breed only during certain seasons (Ch. 8), others only at approximately monthly cycles, still others at 5-day cycles, and so on. We are most familiar with the monthly and shorter cycles⁷⁴ in non-seasonal breeders.

As previously noted, the female sex cycle is controlled by the interplay between two classes of hormones: (1) the pituitary or gonadotropic hormones, which stimulate the ovary to produce estrogenic hormones; (2) the estrogenic hormones produced by the ovary under the influence of the pituitary gonadotropic hormones. These estrogenic hormones depress the pituitary production of gonadotropic hormones; the activating stimulus for the ovary to produce estrogens is thus removed. In this way there is brought about an oscillatory or periodic cycle of high pituitary gonadotropic hormone production and high ovarian estrogen production. This cycle continues from puberty until the menopause⁷⁵, when the ovary ceases to respond to the high gonadotropic hormone. Gonadectomy in either sex, or absence of sexual development, is associated with a permanent elevation of gonadotropin excretion⁷⁶.

The estrogenic hormones are very concentrated in the egg follicles (ovarian and graafian follicles). Allen and Doisy (1922) injected the fluid from these follicles into castrated mice and rats, bringing about the cycle without the presence of the ovary. The course of the cycle is followed most easily by changes in the appearance of the vaginal smear (Stockard and Papanicolaou, 1917) and is used for estimating the potency of the estrogen hormone (Edgar Allen and Doisy, 1922). This method for assay of the hormone led to its ever greater purification and final isolation (Doisy, 1929).

The steps in the estrus cycle are roughly as follows:

(1) Beginning with puberty, the pituitary (gonadotropic hormones) activates the ovary (and perhaps other tissues) to produce estrogen hormones

(2) The estrogen hormones stimulate growth of most sex organs, especially the ovarian (graafian) or egg follicles, ripening of the eggs, ovulation, *i.e.*, shedding of the eggs from the ovarian follicles, and the phenomenon of estrus⁷⁷. Estrus is what farmers call heat, or sexual receptivity, when fertilization may occur.

⁷⁴ Cf. Guthrie, Mary J., "Reproductive cycles in animals," *Growth*, **3**, 261 (1939).

⁷⁵ Sub-human or sub-anthropoid species, apparently, do not have a menopause (sudden cessation of reproductive activity); the reproducing ability seems to decline gradually until the end of life. Also human males do not appear to have a sudden climacteric comparable to the menopause in women, but a gradual decline.

⁷⁷ "Estrus (or oestrus) means 'periodic sexual excitement of the female,' but estrum means *any* recurrent excitement," G. W. Corner, *Science*, **85**, 197 (1937).

(3) After the eggs are shed from the egg follicles, the latter become endocrine organs called corpus lutea, producing another hormone, progesterone, which controls the implantation and nourishment of the fertilized egg in the uterus, including formation of the placenta.

(4) If no fertilization occurs, this growth of the uterine bed degenerates, and this whole elaborate receptional structure for the fertilized egg is swept out. In man and most anthropoids, this sweeping out, called menstruation, is dramatic because of the hyperemia and bleeding of the endometrium (lining of the uterus). In other species, it passes unnoticed, without bleeding; these species do not menstruate. It is curious that those species that have a marked estrus do not have marked menstruation, and conversely.

Women have menstruation, that is, a visible bleeding, or sweeping out of the receptional set-up in the uterus, but no estrus, that is, no sexual excitement at the time of ovulation. They are, indeed, unaware of the time of occurrence of ovulation⁷⁸. Ovulation in women usually occurs sometime between the eighth and twentieth day after the beginning of menstruation, when fertilization can occur. In farm and laboratory animals other than anthropoids, fertilization can occur only during estrus, that is, during sexual excitement, which coincides with ovulation.

If the egg is not fertilized, the decline of estrogen hormone production by the ovary releases the pituitary to produce more gonadotropic hormone, and the whole elaborate sex cycle is repeated.

This brief outline illustrates the balance between the gonadotropic and estrogen hormones. The cyclic nature of sex activity is thus a pendulum-like oscillation between pituitary and ovarian activity. This discussion also illustrates the general design and sequence of the processes: egg follicle becomes the corpus luteum after the discharge of the egg, and this structure, which previously produced estrogen (in the follicular solution) for producing estrus in the *female*, now produces progesterone for producing the housing facilities for the *young*. Though differing in function, the progesterone is chemically similar to estrogens and androgens; by a slight change the same material serves as estrogen, as progesterone, as androgen, and as one of several other hormones (Fig. 7.1).

But this is not all. When the infant is born it has to be nourished; thus it comes about that at puberty, when the ovary becomes sensitized to the pituitary gonadotropic hormone and produces estrogen hormones, the estrogen, which is instrumental in maturing the sex organs and ripening the eggs, also acts on the mammary gland causing it, especially the duct system, to grow rapidly. The development of the mammary gland, the apparatus for *nourish-*

⁷⁸ See, however, Rosenzweig, S., *J. Clin. Endocr.*, **3**, 296 (1943), indicating shifting psychic attitudes from the pre- to the post-ovulative phase. For cyclic temperature and metabolism changes, see Rubenstein, B. B., *Endocrinology*, **22**, 41 (1938). For an electro-metric method of timing human ovulation, see Langman, L., and Burr, H. S., *J. Heredity*, **33**, 223 (1942). Too many factors, however, influence the electric potential difference to make it significant [Snodgrass, J. M., *Am. J. Physiol.*, **140**, 394 (1943)].

ing the young, is thus synchronized with that of the sex organs, the apparatus for producing the young.

The milk-secreting alveoli (terminal-chamber) stage of the mammary gland is perfected during gestation under the influence of the progesterone hormone, the same hormone which controls the production and maintenance of the reception and nutritional chamber for the embryo. It should be noted that the effects of the various hormones are confined to specific tissues at definite ages, in definite states of competence to react to the given hormones. The "logistics"—to employ a current military term—of this process thus appear to be, so to speak, arranged with foresight, economy, and the ultimate in perfection of timing. One is tempted to carry the logistics of this reproductive campaign both backward, to the emotional (neuro-psychologic) mechanisms which bring male and female together with all the familiar courtship devices and all the far-reaching social implications, and forward not merely to the production of milk, but also to the development of maternal behavior, found in mice as well as men. These emotions are apparently under the control of neuro-endocrine mechanisms^{78a}. It is interesting to note that in some species, pigeons for example, milk production (pigeons produce about 10 g "pigeon milk" a day similar in composition to rabbit milk—65 to 80 per cent H₂O, 13 to 19 per cent protein, 7 to 13 per cent fat, 1.5 per cent ash) and brooding are shared by both parents, and that for their proper functioning the male must have testes as females must have ovaries. The gonadotropic hormones are probably the same in male and female, and, as noted, the testicular hormones differ only in detail from the ovarian sex hormones.

The discovery that ovarian activity is controlled by anterior-pituitary hormones was made by Smith and Engle⁷⁹ and Zondek and Ascheim⁸⁰. This pituitary control of gonadal activity is demonstrated by: (1) hypophysectomy, which is followed by cessation of sex function, and restoration by pituitary implants⁸¹; (2) naturally sterile dwarfs (mice) become fertile on pituitary implantation⁸²; (3) implantation of mature pituitary tissue⁸³ or injecting gonadotropic preparation⁸⁴ (or testosterone propionate⁸⁵) in infant chicks or rats results in extreme sex precocity (sex "maturity" in 15-day old mice or 10-day old chicks). Cushing⁸⁶ observed some thirty years ago that hypophysectomy is followed by atrophy of the gonads.

So many hormones are referred to the anterior lobe that one wonders whether there

⁸⁶ Cushing, H., "The pituitary and its disorders," 1912.

are special tissues that secrete each of the hormones. Warbritton and McKenzie⁸⁷ reported the recognition of nine morphologically different types of cells in the glandular lobe of the anterior pituitary of the ewe⁸⁸. The anterior pituitary appears to have (1) chromophobe cells which do not stain well, and (2) chromophil cells which do stain well. Of the latter, there are (2a) acidophil cells which stain by acid dyes, and (2b) basophil cells which stain by basic dyes. The lactogenic and growth hormones are attributed to the acidophils, the gonadotropic to the basophils. The growth-hormone production is attributed to the acidophils because of their absence in dwarf-mice⁸⁹ pituitaries and their overabundance in "giants"⁸⁸.

As previously outlined, under the influence of the pituitary gonadotropic hormones, the gonads (testis, ovary) produce sex hormones which control the growth of sex tissues, including mammary gland, secondary sex characteristics, and sex functions in general. The male (testis) hormones are the androgens; the female (ovarian) hormones are of two kinds: (1) estrogens produced mostly in the ovarian follicles, controlling the estrus cycles, including ovulation and mating, and (2) progesterone produced by the corpus luteum, controlling implantation and nutrition of the fertilized ovum. The estrogens are produced under the influence of the (pituitary gonadotropic) follicle-stimulating hormone, or F.S.H.; progesterone is produced under the influence of the (pituitary gonadotropic) luteinizing hormone, or L. H., identical with I.C.S.H. (interstitial cell-stimulating hormone).

The terminology of the sex hormones is involved⁹⁰, as indicated by the following outline, which is by no means generally accepted.

The known female sex hormones are: (1) *estradiol*, the active estrogen principle in the ovaries; (2) *estrone*, or theelin, produced from estradiol in the ovaries, is found in blood and urine in males as well as in females (corpus luteum, placenta); (3) *estriol*, or theelol, produced from estrone in the uterus (the conversion does not occur in the ovariectomized), constitutes about 80 per cent of the estrogen in pregnant urine; (4) *equilin*, and its isomers hippulin and equilenin, have thus far been found in mare urine only.

Assays for sex hormones are growth responses of specialized tissues. Thus the Corner-Hisaw test for progesterone is the growth response of the uterine endometrium; the Allen-Doisy test for estrogen is a growth response of the genital tract including estrus production; the Koch test for male sex hormones is the growth response of comb and wattles of the capon. A test of another category is that for acetylcholine which estrogens release in the uterus. The latest pregnancy test⁹¹ in humans consists in administering prostigmine, which activates the acetylcholine and leads to hyperemia and consequently induces menstrual flow provided the subject is not pregnant.

It was noted that the placenta produces gonadotropic hormone. The time curve of its production with the advance of the period of gestation has been worked out for cattle⁹² and women⁹³. The following, for women⁹³, is timed from the first day that the menstrual period is missed.

Days	3	14	22	36	46	55-66	80	99	4 days after birth
Urinary Hormone per day	150	65,000	125,000	1,040,000	260,000	130,000	65,000	10,400	0

The Ascheim-Zondek pregnancy test previously explained is a test for these urinary gonadotropins. The function of the placental gonadotropins, perhaps, is to stimulate the corpora lutea.

As regards lactation, Grueter and Stricker⁹⁴ in Strasbourg and Corner⁹⁵ in this country demonstrated that this process is under the control of the pituitary.

Some investigators⁹⁴ maintain that milk secretion is the resultant of the action of a series of *distinct* pituitary hormones: (a) lactogenic, which regulates milk production *by direct influence on the secreting cells* of the mammary gland, and (b) several metabolic hormones for protein, carbohydrate, fat, etc., each of which regulates milk production *by its influence on a particular milk precursor*. Other investigators⁹⁶ maintain that the same biochemical entity which stimulates milk secretion by mammary cells, *i.e.*, the lactation hormone, also shows other hormonal properties, among which may be: (1) calorogenic in conjunction with the pituitary thyrotropic hormone; (2) calorogenic in thyroidectomized animals; (3) diabetogenic⁹⁷; (4) crop-secretion stimulant in pigeons; (5) releaser of brooding instinct in fowls and maternal behavior in rats⁹⁸, sustainer of liver, pancreas, and intestines in pigeons; (6) participator in acceleration of growth. However, these may be due to impurities associated with the lactogenic hormone. The "lactation hormone" is customarily assayed by its influence on crop gland growth⁹⁹ in pigeons of either sex rather than by its milk-stimulating property. The theory that the same substance which stimulates mammary-gland cells to produce milk also induces maternal behavior gives a functional unity to a diversity of phenomena.

The mechanism of mammary-gland growth is at present under investigation. The following notes represent the ideas of my department colleagues¹⁰⁰ as summarized in Fig. 7.3b. The mammary gland is made up of several components, including the stromal connecting tissues which house the vascular system and glandular tissue, and the parenchymatous tissue (ducts, alveoli, lobules, etc.)—the milk-conducting and -secreting tissues.

As regards the parenchymatous tissues, at birth they usually consist of the primary ducts from which secondary ducts have sprouted. The mammary duct tree develops during the recurring estrous cycles of puberty while the mammary lobule-alveolar system (terminal-chamber secreting system) develops during the first half to two-thirds of pregnancy. The hypertrophy of the gland preceding parturition is not due to growth

⁹⁴ Turner, C. W., in Edgar Allen's "Sex and Internal Secretions."

⁹⁷ However, Bergman and Turner reported [*Endocrinology*, 22, 619 (1938)] chemical separation of lactogenic and carbohydrate-metabolism anterior-pituitary hormones. Also, Bergman, A. J., and Turner, C. W., *J. Dairy Sci.*, 23, 1229 (1940).

⁹⁸ Riddle⁹⁶. However, Leblond and Nelson [*Am. J. Physiol.*, 120, 167 (1937)] reported maternal behavior in hypophysectomized animals.

⁹⁹ Bates, R. W., *Cold Spring Harbor Symposia on Quantitative Biology*, 5, 191 (1937). Lyons, W. R., *Symposia on Quantitative Biology*, 5, 198 (1937). The discovery of this crop test and that the pituitary extract that contains the lactogenic hormone is identical with the extract that gives this crop test are due respectively to Riddle, O., and Braucher, P. F., *Am. J. Physiol.*, 97, 617 (1931), and Riddle, Bates, R. W., and Dykshorn, S. W., *Id.*, 105, 191 (1933). Riddle named this pigeon-crop factor "prolactin". Others named it later galactin, lactogen, lactogenic hormone, mammotropin, and so on. One cannot be certain of the role of this factor in milk production, since milk production is dependent on many interrelated hormones, for example, thyroxine and cortin factors.

¹⁰⁰ Mixner, J. P., and Turner, C. W., Univ. Missouri Agr. Exp. Sta. Res. Bull. 378, 1943. C. W. Turner in Edgar Allen's "Sex and Internal Secretions". Riddle, O., *J.A.M.A.*, 115, 2276 (1940).

but to swelling with secretion. There is apparently little growth of the gland during lactation, unless pregnancy occurs simultaneously, in which case there may be additional gland growth.

It is now generally believed that mammary growth is under direct pituitary control. Corner¹⁰¹ was the first to report that he observed development of the mammary glands of young castrated rabbits under the influence of injections of an alkaline extract of sheep anterior pituitary. Turner *et al.*¹⁰² first demonstrated that the presence of the pituitary is essential for mammary growth, the ovarian hormones being ineffective in the absence of the pituitary. The present theory, based on research in the Missouri laboratory, is that estrogen (during puberty and estrus) stimulates the pituitary to an increased secretion of a mammogenic duct-growth hormone, whereas progesterone (during gestation) stimulates the pituitary to an increased secretion of a mammogenic lobule-alveolar-growth factor. Estrogen causes an increased hyperemia and vascularity of the stromal tissue associated with an increased permeability of the vascular system¹⁰³. Thus more rapid growth of the mammary gland is promoted indirectly by increasing the amount of pituitary mammogen and nutrients present in the intercellular spaces in the region of the mammary gland. This action of estrogen explains the so-called "local action" of estrogen in promoting mammary growth reported by Lyons¹⁰⁴, Speert¹⁰⁵, and others. This action of estrogen is dependent upon the presence of a circulating pituitary mammogen.

Summarizing, while the rate of mammary growth may be influenced by many factors (for example, the thyroid and adrenals), the mammary gland is the specific target gland of the pituitary. The ovarian hormones, estrogen and progesterone, act on the pituitary to stimulate increased amounts of mammogenic factors. Estrogen in addition causes an increased hyperemia and permeability of the vascular system.

The mammogenic hormones are protein in nature. Their possible identity with other pituitary hormones has not been fully investigated, although it is probable that the lobule-alveolar-growth factor is not the same as lactogen, thyrotropin, or gonadotropin.

As regards the mechanism which initiates lactation, it appears¹⁰⁶ that estrogen is the primary stimulator of the lactogenic hormone produced by the pituitary. During pregnancy progesterone checks the estrogen action. At parturition progesterone production decreases, the inhibiting effect on estrogen is removed and lactation proceeds. Once lactation is established, the stimulus of suckling or milk removal reflexly stimulates the periodic release of lactogenic hormone from the pituitary.

It is not possible to discuss the influence of prolactin administration on the efficiency of milk production. All that we know is that injection of a crude extract¹⁰⁷ of the anterior pituitary gland, and in some cases stilbestrol, may show, among other effects, initiation of milk production¹⁰⁸.

7.2.1: Some applications of sex endocrinology. The evolutionary and agricultural advantage of this complex process of sexual reproduction—as contrasted to asexual and other simpler reproductive methods not involving the complex neuro-endocrine mechanism (see Sections 10.8 and 10.9)—is that it promotes most diversification in the offspring. This favors the best evolutionary and agricultural selection, or “survival of the fittest”, under the given environmental conditions. The improved breeds of farm animals and plants were, of course, achieved by such selection from variant individuals, each a carrier of highly diverse genes.

A curious feature of some practical importance is the difference in sex mortality. In man, at any rate, the male mortality is consistently above that of the female, and the same appears to hold for other mammals. One possible explanation for the higher male mortality is that the (maternal) female hormones may exert a lasting injury on the male offspring during his physiologically prolonged sojourn *in utero*, that is, assuming an antagonism between female and male hormones.

That there may be an antagonism between male and female sex hormones (depending on dosage) is indicated by the fact¹⁰⁹ that of the twin calves of opposite sex, the female (called “free martin”) seems to lose her sex function permanently by prenatal commingling of the blood of the two sexes. Pituitary gonadotropins are produced prenatally, as indicated by the sex-stimulating effect of fetal pituitaries¹¹⁰. There is other evidence of sex-hormone antagonism, as indicated by atrophy of male genitals by injecting large amounts of female hormone¹¹¹. However, the male organs are also injured by injecting male sex hormone¹¹².

It is more reasonable to attribute the higher mammalian male mortality to his constitutional difference—to his having one unpaired or X-chromosome. It is generally known that there are two kinds of mammalian sperms, female-producing, having paired or even number of chromosomes, and male-producing, having unpaired or odd number of chromosomes (the opposite is true for birds and butterflies). Mammalian males having only one, the X-chromosome, carry as dominant some characters which in the female are masked by the complementary genes in the Y-chromosomes. Some of the unmasked characters, such as hemophilia, are very dangerous in the male but harmless in his mother because of protection by the complementary Y gene in the female chromosome. Color blindness and baldness are well-known harmless dominants in men which are recessive in women.

The literature on the influence of experimental manipulation of sex-hormone level on growth and development is large and confused because it varies with species, race or family within the species, individuals within the family, sex, age, length of time of hormone administration, period following the hormone administration, hormone dosage, diet, and so on.

By way of introduction it may be recalled that, in general, development or maturation is more rapid in females than in males¹¹³; also that breeding females often grow to be larger than non-breeding¹¹⁴. The results on human

growth (see Fig. 16.62, the ratio of the growth rate of girls to boys) are in agreement with those on other mammals. Ossification tends to be somewhat more rapid in girls than in boys, even during prenatal and prepubertal life¹¹⁵ and the onset of puberty accentuates these differences¹¹⁶. The differences between the sexes evidently are partly genetic, and independent of the sex hormones, since, as previously explained, there are prenatal and prepubertal developmental differences which extend to differences between early gonadectomized males and females; there are also sex differences resulting from hormonal action, since the pattern of sex behavior in each sex, especially in the female, is influenced by administration of sex hormone from the opposite sex.

The foregoing introduction may be useful in interpreting the experimental data on the effects of gonadectomy and sex-hormone administration.

Estrogen administration to normal females for considerable periods tends to inhibit growth of the long bones, thereby retarding growth¹¹⁷. Precocious sexual maturity in girls is often associated with short legs¹¹⁸; on the other hand, excessive limb growth has been checked by estrogen administration¹¹⁹. Estrogen administration to growing mice increased the breaking strength of bones¹²⁰ but did not affect the bone length¹²¹.

The influence of sex-hormone administration or removal may be by the intermediacy of the pituitary¹²² and thyroid¹²³, which lead to rate differences in epiphysal closure, ossification of the bone matrix¹²⁴, aging of cartilage¹²⁵, and so on¹²⁶.

Progesterone tends to neutralize the estrogen effects¹²⁷. While estrogen depresses the growth rate, progesterone stimulates it¹²⁷. This may explain

the fact that pregnancy stimulates the growth of the mother¹²⁸ despite the increased estrogen production at that time.

Gonadectomy in males is usually followed by immediate growth retardation, although ultimate growth acceleration may result¹²⁹. Gonadectomy of females on the other hand is usually followed by immediate growth acceleration, although there may be later growth retardation¹³⁰.

Ovariectomy probably stimulates growth by removing the growth-inhibiting effect of estrogen, although not as much as gestation¹³¹. The effect depends on the age of ovariectomy. Freudenberger¹³² ovariectomized 47-g rats at age 4 weeks. At the age of 6 weeks the ovariectomized rats weighed 4 per cent more, at 7 weeks 8 per cent, and at 13 weeks 20 per cent more than the normal controls (the ovariectomized rats weighed 205 g; the controls 171 g). The visceral-organ weights of the ovariectomized rats were greater than those of the control by 77 per cent for thymus, 23 per cent for spleen, 18 per cent for pituitary, 17 per cent for lungs and digestive tract, 13 per cent for heart and liver, 10 per cent for thyroid and adrenals, 8 per cent for kidneys, and 4 per cent for body and tail length.

While early gestation stimulates growth and increases the mature size of the mother (Fig. 7.4), early breeding of dairy cattle¹³³, swine¹³⁴, and sheep¹³⁵ retards growth because of the drain of heavy lactation (not gestation). Early-bred heavily-lactating animals usually reach normal size but at a later age, requiring a longer period to attain normal size. Early-bred heavily lactating rats invariably reach normal size, often super-normal size¹³⁶, if properly fed.

Cole and Hart¹³⁷ bred young rats and found no harmful effect of lactation on the growth of the immature mothers. However, the litter size was reduced at birth to 4 to 6 young, and the mothers had access to an excellent diet. The average litter size in this strain of rats was reported to be 11.5 with a range of 1 to 19. These investigations report remarkable growth acceleration (by about 16 per cent over the controls) of the mothers by frequent pregnancies. The growth-accelerating effects of pregnancy on the mothers were interpreted to mean that pregnancy stimulates the pituitary to secrete growth hormones. "Pregnancy is intermediate in its growth stimulus between that occurring

in virgin controls and rats regularly treated with maximum stimulating amounts of growth hormone". As previously noted, the growth-stimulating effect of pregnancy is also attributed to progesterone rather than to pituitary growth hormone.

While ovariectomy tends to stimulate growth (by removing the inhibiting effect of estrogen), orchidectomy (testis removal) tends to depress growth and mature size¹³⁸. Stallions and bulls tend to be larger than geldings and steers. This harmonizes with the previous statement that within limits androgen, but not estrogen, tends to increase growth and mature size. There are some exceptions; when ovariectomized or orchidectomized early enough, man tends to be above normal height because of delay in epiphyseal closure.

Farm male animals are castrated in order to reduce restlessness and spontaneous activity¹³⁹ (which is, of course, at a feed cost), to facilitate fattening, to increase palatability of the meat, and to increase the dressing percentage.

The data in Tables 7.1 and 7.2 on the growth of normal and castrated lambs¹⁴⁰ and domestic fowl¹⁴¹ illustrate the situation.

We shall close by considering the question whether or not sex hormones can increase reproductive efficiency in good, normal farm animals by speeding up the reproductive process. Theoretically, breeding may begin earlier and animals may be induced to produce larger litters. Actually, the normal breeding age in good, normal animals is probably early enough and the normal litter size is probably large enough for the mother's capacity¹⁴².

¹⁴² Phillips, R. W., *et al.*, *J. Animal Sci.*, **1**, 27 (1942).

There is a large literature on superovulation or superfecundity in mammals treated with various gonadotropic preparations¹⁴³. Casida¹⁴⁴ obtained twinning in cattle by injecting F.S.H. preparations followed by artificial insemination, and Loginova¹⁴⁵ induced the production of quintuplet lambs by treating ewes with pregnant-mare serum. Engle¹⁴⁶ obtained up to 29 implanted embryos on the ninth day of pregnancy in mature mice receiving pituitary transplants. However, the size of the *delivered* litter was not unusual. Evans demonstrated that superovulation does not increase the number born¹⁴⁷.

TABLE 7.1.—Influence of Castration on Growth, Carcass Weight, and Dressing Percentage of Lambs.

tained 26 normal fetuses on the seventeenth day of pregnancy; another had 23 living fetuses on the twenty-first day. In some cases 17 living young were born. The young mothers were not injured by the early pregnancies and extraordinarily large litters, but actually increased in body weight and in length beyond the control animals.

An interesting aspect of Cole's experiments is that the influence of pregnant-mare serum gonadotropic hormones on litter size in rats rapidly decreased with the age of the mother. In mice^{147a}, on the other hand, superovulation was induced in mature animals with pituitary implants, and in cats¹⁴⁸ by subcutaneous injection of F.S.H. followed by the intravenous injection of L.H.

Research is being conducted on the induction of fecundation in seasonal breeders, especially sheep, during the non-breeding season¹⁴⁹. Estrogen administration (stilbestrol and pregnant-mare serum) led to off-season estrus and ovulation but not to fecundation in sheep¹⁵⁰. Adjusting the light-to-dark ratio to simulate the natural-breeding season seems promising in view of the results reported by Bissonnette on goats and other species (Ch. 8). Thyroid administration is said to be promising in inducing breeding during the non-breeding season¹⁵¹.

Minor applications are under investigation, such as the treatment of recurrent or threatened abortion with progesterone¹⁵².

Summarizing, this section (7.2) outlines the role of sex hormones in reproduction, efficiency of agricultural processes, evolution, growth and development and life in general. The reproductive process, however, is not dependent on sex hormones alone but on all hormones acting in harmony, as well as on diet, and on season. This section is, therefore, incomplete by itself; it must be considered in conjunction with all the other sections in this chapter as well as with chapters 6 and 20 (nutrition) and 8 (seasonal effects).

The endocrinology of reproduction illustrates a frequently encountered pattern of endocrine action. The reproductive process is under the control of the gonads (ovaries and testes), and the gonads are under the control of the anterior lobe of the pituitary. In addition, other endocrines, for example, the thyroid and the adrenal cortex, participate in the reproductive and lactation processes. The gonadotropins and sex hormones are produced by the pituitary and by the gonads respectively; but gonadotropins are also produced by the placenta and perhaps other tissues, and sex hormones may also be produced by the adrenal cortex (Sect. 7.4). The gonadotropins are usually excreted with the urine; but in gestating horses the blood is very rich in

gonadotropins¹⁵³. Yet, unlike gonadotropin in women, it is not excreted in the urine, perhaps because, unlike other gonadotropins, the mare's placental gonadotropins are more complicated, and are apparently in peptide form¹⁵⁴. The sex hormones are thought to be excreted in the urine; but stallions and bulls excrete mostly female, not male, sex hormones; perhaps the hormones in the urine are not the original sex hormones. There are evidently species, sex, and age differences. There are rules and rule exceptions. The mare blood-serum gonadotropin is apparently very potent; its intravenous injection in 36 women on varying days of the menstrual cycle induced ovulation¹⁵⁵.

7.3: Energy-metabolism hormones, thyroid and adrenal-medulla. All hormones are energy-metabolism catalysts. This section is concerned with the best-known energy-metabolism endocrine, the thyroid, with brief notes on the adrenal-medulla, and on their interrelations with other endocrines and with the nervous system.

As might be expected, there is a large literature on the thyroid, its anatomy¹⁵⁶, evolution¹⁵⁷, chemistry¹⁵⁸, pathology^{156,159}, and so on.

7.3.1: The thyroid in growth, development, milk production, and egg production. Modern thyroid research, that is, one involving thyroid removal and replacement therapy, began over half a century ago¹⁶⁰. It is now generally known that myxedema is associated with thyroid loss or deficiency in the adult and cretinism with thyroid absence or deficiency from early life. On administration of thyroactive material, developmental normality may be resumed under certain conditions.

This situation is demonstrated by surgical removal of the thyroid in infant animals and noting the course of growth and development of the animal with and without thyroactive medication. Fig. 7.5 represents a recent attempt to produce cretin cattle¹⁶¹ by surgical removal of the thyroid (thyroidectomy at 50 days of age). The mature body weight is seen, in Fig. 7.5, to be half normal and the energy metabolism per unit urea 40 per cent below the normal control.

Similar results are available on rabbits, goats, sheep¹⁶², mice¹⁶³, guinea pigs¹⁶⁴, cats¹⁶⁵, rats¹⁶⁶, monkeys¹⁶⁷, dogs¹⁶⁸, chickens¹⁶⁹, and other species¹⁷⁰.

the other hand, feeding thyroid to small tadpoles metamorphoses them into pigmy froglets¹⁷². Indeed, one assay method for thyroid activity is to determine the dosage for transforming a tadpole into a frog¹⁷³. The Mexican aquatic lizard *axolotl* normally spends its life in this ("tadpole" or larval) form. On feeding thyroid it is changed to the terrestrial (lung-breathing) salamander (uradele) *ambystoma*, and this metamorphosis is likewise used as assay for thyroxine hormone¹⁷⁴. It is evident that the thyroid has developmental and differentiating factors as well as growth functions.

Cretin animals have a typical appearance: short legs, short dished (bulldog) face, rough dry skin and hair, "pot-belly", and so on. Sheep thyroidectomized between one and five months developed some characteristics of primitive sheep. The long bones and epiphyses fail to grow out. The effect of thyroid

Fig. 7.5e—Comparison of resting heat production of the same cattle.

removal depends on the age at which it is performed. In our experience¹⁶¹ the earlier the age of thyroidectomy the more severe the results¹⁷⁵, although Hammett¹⁷⁶ reported the opposite.

About 1895 Magnus-Levy¹⁷⁷ discovered that loss of the thyroid may reduce the basal energy metabolism by nearly half, and that suitable thyroid feeding

may almost double the metabolism. Metabolic rate was, therefore, generally adopted as a measure of thyroid function. More recently, thiourea and related anti-thyroid compounds have been investigated as assay agents¹⁷⁸.

The acceleration of bodily oxidation is, however, only one of the thyroid's catalytic manifestations. Dinitrophenol may be used to raise to normal the energy metabolism of a thyroidectomized animal but not the growth or development rate. In fact, all anabolic processes are retarded by thyroidectomy, including the rates of digestion¹⁷⁹, peristalsis¹⁸⁰, assimilation, especially of carbohydrates¹⁸¹ (perhaps associated with decreased phosphorylation), circulation rate¹⁸², milk production¹⁸³, egg production¹⁸⁴, muscular activity¹⁸⁵, nervous irritability¹⁸⁶, and so on. There is a possibility that the thyroid elaborates more than one active principle, perhaps one which accelerates the pulse rate independently of increased metabolism¹⁸⁷.

Hypothyroidism is associated with a tendency to fattening. This suggested the investigation of the influence of partial thyroidectomy, surgical or perhaps by anti-thyroid drugs (as thiourea) administration, on the fattening of farm animals. Partial surgical thyroidectomy is said to yield desirable results in fattening steers¹⁸⁸, and also pigs¹⁸⁹ thyroidectomized when weighing 30 to 40 kg, but not at later ages. Zorn¹⁸⁹ concluded that the feed utilization was shifted to a lower efficiency level, from muscle and skeletal growth to fattening. (It requires more dietary energy to produce a calorie of fat than of carbohydrate; the exact cost depends on the nature of the diet, age, and other conditions.) The term "fattening" under these conditions is ambiguous unless accompanied by data on the composition of the gains¹⁹⁰.

It is human to assume, as did Moussu¹⁹¹ in 1899, that if some thyroid is essential for normal growth, a little more thyroid would result in supernormal growth, and he indeed reported acceleration of the growth rates in normal dogs by feeding small amounts of thyroid tissue. The growth, however,

stopped earlier than in the controls, and mature size was slightly subnormal. This 1899 result on dogs was confirmed in 1923 by Dott¹⁹². Thyroid medication accelerated growth, and was followed by premature cessation of growth with ultimate somewhat subnormal size. A considerable literature has developed since Moussu's report.

Much of this literature¹⁹³ on the influence of thyroid administration on growth is conflicting because of the variability of the thyroid effect with species, age, sex, external temperature and particularly dosage. There is one physiologically optimal thyroid-dosage level. Below this level the results are not impressive because the animal's thyroid probably reduces its own hormone production in proportion to the amount of thyroid administered (in accordance with the principle of homeostasis, Ch. 10). Above the optimal level, the catabolic effect of the thyroid hormone overbalances the anabolic effect; indeed, the extra hormone often becomes toxic.

This optimal thyroid dosage, moreover, varies with the external temperature¹⁹⁴ (Ch. 11) and with the species. Thyroid administration increases heat production; therefore, animals having a good heat-dissipating mechanism would naturally be expected to do better under thyroid treatment than species not so well equipped for heat dissipation.

Then, too, thyroid administration increases the neuro-muscular irritability in particular and variability in general¹⁹⁵. This is not unexpected, since thyroid accelerates the metabolism of nerve tissue¹⁹⁵ and affects corresponding neuromuscular activity¹⁹⁶, cortical alpha rhythms¹⁹⁷, thresholds to light and sound¹⁹⁸, and so on. This exaggerated variability of hyperthyroid animals complicates the interpretation of the results of thyroid-hormone administration.

There is a particularly striking species variability in the reaction to thyroid administration. Thus the growth rate of mice is increased by a certain thyroid dosage. This was observed by Robertson¹⁹⁹ (who fed the equivalent of 19 mg fresh thyroid per animal per day), and recently confirmed²⁰⁰, by daily

²⁰⁰ Koger and Turner¹⁹³.

injection of 0.01 to 0.03 mg crystalline thyroxine). The mature size was not changed; only the maturation rate or early growth rate was accelerated. Thyroid administration to young mice and dogs accelerates the growth of the epiphysial cartilage and thus leads to premature epiphysiodiaphysial union²⁰¹.

Rats might be expected to react to thyroxine as do mice. But Koger and Turner²⁰⁰ could not accelerate the growth of rats, guinea pigs, or rabbits by any thyroid dosage. There is evidently a species difference. Moreover, different strains of rats reacted differently to a given thyroid dosage and females appeared to tolerate the hormone better than males²⁰². The growth rate of the smaller breeds of domestic fowl is apparently accelerated by thyroid administration, but not of the larger²⁰³.

The growth of some children is accelerated by feeding about 1 grain (65 mg) of desiccated thyroid per day. This favorable response of *some* children was explained by one author as due to a "masked hypothyroidism"²⁰⁴. The results are suggestive, but the individual variations in response cast doubt on its significance for the practical acceleration of the growth process.

A noteworthy observation by Koger and Turner²⁰⁰ is that the total energy stored was the same in the growth-accelerated and control mice, the difference in size being due solely to differences in the storage of water, protein, and fat. The thyroid-dosed mice had a higher water and nitrogen and a lower fat content.

The other thyroid-feeding effect, long known, is hypertrophy of the heart, liver, spleen, and adrenals²⁰⁵. The pancreas tends to hypertrophy and the insulin content is increased²⁰⁶. Of course, the thyroid gland is depressed²⁰⁷ (Sect. 7.1) in accordance with the principle of homeostasis (Ch. 10) and so is the pituitary²⁰⁸.

As regards the influence of thyroid on other productive processes, it is generally known that thyroid medication is useful in some cases of human

sterility²⁰⁹. It may be similarly useful in farm-animal sterility, especially with the loss of fertility during aging²¹⁰.

Crew²¹¹, indeed, published spectacular observations on "rejuvenation of the aged fowl through thyroid medication". He used 5 cocks and 7 hens, 5 to 8 years of age, "all showing the classical signs of old age". The medication consisted in feeding desiccated thyroid equivalent to 0.2 mg iodine per day during the first fortnight, 0.4 mg iodine per day the second fortnight, and 0.8 mg iodine per day thereafter ("no control pan was maintained", a rather serious methodologic deficiency). The hens "quickly started to produce eggs at a faster rate . . . head furnishings became red and turgid, the plumage tight and close . . . all the birds became rejuvenated, looking fresh and being active . . . none of the hens became broody during the course of the experiment (12 months), though six out of the seven belonged to the setting breeds". Three months after cessation of the thyroid feeding "they became progressively senile", two dying from roup and pneumonia, two from peritonitis associated with oviduct rupture, one "died of what must be diagnosed as old age, no organic lesion was present . . . all the hens that are still active exhibit the classical signs of ovarian atrophy". It is strange that no one followed up this work in spite of the universal interest in rejuvenation and the extremely important agricultural implications of this observation.

Preliminary observations²¹² on two-year old Leghorn hens indicate greatly increased egg production over several months associated with feeding thyroactive material at a certain level. It is, of course, known that the thyroid is involved in egg production, and that thyroidectomy in mature fowls severely reduces egg production²¹³ which may be restored by suitable thyroid feeding.

There is also considerable literature²¹⁴ indicating that milk production in dairy cattle may be increased up to 20 per cent and fat production up to 50

per cent, at least for short periods on the declining segment of the lactation curve, by feeding thyroactive material (15 gm iodinated casein daily). However, the ascorbic acid content (no data on other vitamins) in the milk is reduced²¹⁵.

From the homeostatic viewpoint (Ch. 10) one would infer that it is not safe to meddle with a naturally evolved physiological system by upsetting the normal balance, as is done by thyroid or other drug administration. Thus long-continued thyroid administration tends to lead to thyroid atrophy, adrenal hypertrophy²¹⁶, damage of the circulatory-renal²¹⁷ and hepatic²¹⁸ systems, and accelerate the rate of senescence²¹⁹. But, as above noted, such injuries, even if present, may be without agricultural significance when, for example, thyroid is fed to three year-old hens the last year before slaughter.

Inexpensive iodinated casein²²⁰ and iodinated peanut protein²²¹ preparations are available, as well as crystalline-*d-l*-thyroxine²²² and also *l*-thyroxine²²³, which may be used conveniently for experimental and feeding purposes.²²⁴

It appears that Morse²²⁵, in 1914, demonstrated that protein treated with iodine exerts thyroxine effects. Subsequently, several investigators²²⁶ demonstrated the presence of thyroxine in casein and other protein treated with iodine.

It should be noted, in conclusion, that, as might be expected, thyrotropic hormone exerts effects (by way of thyroid) similar to thyroxine; thus there appears to be a correlation between thyrotropic hormone concentration (in the anterior pituitary) and the growth rate²²⁷.

7.3.2: Other thyroid interrelations. The preceding section was concerned with the influence of thyroidectomy and thyroid medication on agriculturally

productive processes, growth and development, egg production, and milk production. This section is concerned with other thyroid interrelations, particularly those with diet and with other hormones.

A. Thyroid and nutrition. Thyroid administration, or hyperthyroidism, accelerates all metabolic processes. Hyperthyroidism is consequently associated with a correspondingly increased need for all nutrients—proteins, minerals, and vitamins. If the calorie and protein needs are satisfied but the vitamin needs are not, hyperthyroidism obviously will be associated with and show symptoms of hypovitaminosis. Such cases have been definitely reported for thiamine^{228, 229} and less definitely for pyridoxine and pantothenic acid²²⁹. The cardiac symptoms²³⁰ (bradycardia and tachycardia) and hepatic damage (particularly low liver glycogen²³¹) associated with hyperthyroidism are confused by the cardiac and hepatic syndrom associated with insufficiency of the B vitamins, particularly of thiamine.

While there is a large literature²³² indicating some "antagonism" between thyroxine and the B vitamins, this may be true only in the sense that thyroxine accelerates all metabolic processes, with a consequent increase in need of the vitamins. Hypovitaminosis effects are probably secondary to primary hyperthyroidism.

Hyperthyroidism increases the requirements for vitamin A, as for other vitamins. But there are, in addition, other interrelations between vitamin A and thyroxine. One of these is that vitamin A deficiency leads to thyroid hypertrophy and degeneration of the epithelial cells²³³. This, however, is not an exclusive property of vitamin A. A second, more characteristic, effect is that vitamin A (fish liver oil) excess depresses not only thyroid activity but apparently the effect of thyroxine as well.^{*} As little as 1 per cent cod liver oil in the stock diet of rats during 4 months reduced the thyroid weight²³⁴.

The body weight loss associated with thyroid administration may be reduced or prevented by sufficient vitamin A administration²³⁵. It has long been known that excess vitamin A delays metamorphosis in amphibians²³⁶,

and it was observed more recently that vitamin A administration partially counteracts the acceleration of energy metabolism following thyroid feeding²³⁷.

A third interrelation between vitamin A and the thyroid is that carotene cannot be converted to vitamin A in the absence of the thyroid. Hence, the prevalence of xerophthalmia in thyroidectomized animals, such as rabbits²³⁸, which normally obtain their vitamin A from carotene. The yellow color of milk produced by thyroidectomized goats that normally produce a white milk²³⁹ is similarly explained.

The above results indicate that high intake of fish-liver oil should be very helpful in hyperthyroid- and Graves'-disease conditions; and that hypothyroid individuals should receive vitamin A as such, and not as carotene. Hyperthyroidism increases the need for ascorbic acid as it does for the A and B vitamins, and ascorbic acid deficiency in guinea pigs leads to hemorrhagic infiltration and hyperplasia of the thyroid gland.

High ascorbic acid dosage appears to decrease the energy metabolism in hyperthyroidism²⁴⁰. Hyperthyroid individuals should, therefore, benefit by high ascorbic acid intake, as by high vitamins A and B intake.

While little is known about the interrelation between vitamin D and thyroid function, it is definitely known that hyperthyroidism greatly accelerates calcium catabolism²⁴¹, perhaps in proportion to the increase in energy in protein catabolism²⁴², which may reach 100 per cent above the normal level.

The foregoing discussion indicates how dietary factors may exert hormone or anti-hormone effects because of their interrelations with endocrines or the hormones. There are many such interrelations, such as those between vitamin E and the pituitary (Chs. 6 and 20). The "pituitary-like effects of yeast extracts"²⁴³ may be explained by similar mechanisms.

Needless to say, the thyroid function is dependent on iodine supply (Chs. 6 and 20). The thyroid holds $\frac{1}{3}$ to $\frac{1}{2}$ of the total (about 40 or 50 mg) body iodine in man. Iodine is taken up to saturation by the gland within 15 minutes after iodine-solution injection²⁴⁴. Thyroxine contains 65 per cent iodine; U.S.P. desiccated whole thyroid contains 0.17 to 0.23 per cent iodine. The iodine content of the thyroid is lowest in early spring and highest in late summer (Ch. 8). Iodine deficiency leads to thyroid abnormalities ranging from relatively harmless goiter to serious cretinism. Both of these and other thyroid abnormalities are found in man and animals depending on the iodine content of the soil

in given geographical regions^{246, 246}, (Northwest, Mississippi Valley, Great Lakes, St. Lawrence Valley, the Andean plateau in South America) and in Europe (Alps, Pyrenees, Carpathians, also Himalayan Plateau in Asia). In these goitrous regions the diet of man contains less than 0.04 mg iodine per day; it should contain 0.1 mg (100 gamma), to maintain the body iodine at the optimum level of about 50 mg ($\frac{1}{2}$ of which is in the thyroid gland). The average human body contains, perhaps, 12 mg thyroxine.

While dietary deficiency of iodides—like that of chlorides—may be followed by serious physiologic disturbances, the opposite, namely, moderate dietary excess of iodide—like moderate dietary excess of chloride—is simply excreted, probably without physiologic disturbance. About 70 per cent excess dietary iodide is excreted in feces, the remainder in urine and, in dairy cattle, in milk²⁴⁷. Blood iodide may be increased ten times normal by dietary means with corresponding iodide increases in milk without apparent harm to the animal²⁴⁷.

Thyroid abnormalities resulting from dietary iodine deficiency are now prevented by the use of iodized salt. This salt contains one part of NaI, or KI, in 5000 parts of salt (0.02 per cent, or one ounce in 300 lbs salt, or 1 part of iodine per million of salt²⁴⁸).

Iodine intake is not helpful in athyreosis. In this case, desiccated thyroid is fed or thyroxine is injected. When the basal metabolic rate is 20 per cent below average (in humans), 1 to 1½ grains (65 to 100 mg) U.S.P. thyroid is taken daily²⁴⁹. Cretins are given $\frac{1}{8}$ to 1 grain up to 4 years, 1–2 grains 4 to 12 years.

According to the review by Boothby and Saniford²⁵⁰, the calorogenic effect of 1 mg thyroxine administered intravenously is about 1000 Calories. This value is based on the observation of the effect of a given dose on a given individual or set of individuals in a certain condition. But the calorogenic effect per mg thyroxine necessarily changes with increasing dosage level and varies with conditions. Thus Meyer and Wertz²⁵¹ reported that thyroidectomized animals are very much more sensitive than normal to a given thyroxine dose. The response tends to be inversely proportional to the initial level of metabolism.

An apparently curious aspect about thyroid administration is that it often improves not only the hypothyroid, but also the hyperthyroid individual. Thyroid administration was observed to lower the metabolism by 30 per cent (to normal) in some cases of hyperthyroid adenoma in exophthalmos²⁵².

B. Thyroid and adrenal medulla. Adrenaline, produced by the adrenal medulla, is related to thyroxine chemically as well as physiologically. Chem-

ically, both are tyrosine derivatives, as indicated by the following. Adrenaline²⁵³ may be thought of as derived from one molecule of tyrosine,

while thyroxine,

an aromatic ether, is derived from two molecules of tyrosine, with the elimination of the side chain of one²⁵⁴.

While both adrenaline and thyroxine are metabolic (oxidation) catalysts, the time relations of their effects are different. The influence of the thyroid on metabolism is of the long-range steady type. The adrenal (medulla), on the other hand, influences metabolism under emergency conditions, controlling explosive outbursts of energy for short-time intervals. The adrenal medulla is a typical "alarm" gland.

It is generally accepted that there is close interrelation between the adrenal medulla and the sympathetic (autonomic) nervous system (Ch. 10). Thus splanchnic stimulation increases adrenaline secretion, whereas splanchnic removal decreases it. Stimulation of the sympathetic system by drugs, as metrazol, or by electric means, resembles the effect of adrenaline administration. The animal shows an emergency syndrome with such symptoms as increased blood pressure, pounding of heart, "standing-up" of hair, increase in respiration, shunting of the blood to the muscles, blanching of skin, and so on.

The large literature on the interrelations between the adrenal medulla and the sympathetic nervous system is best generalized by Cannon's²⁵⁵ "emergency theory". According to this theory, under stress or emotion the physiologic resources are mobilized for action through the agency of adrenaline acting on the sympathetic system. The dis-

²⁵³ For the original chemical papers, see Abel, J. J., "Method of preparing epinephrine," *Bull. Johns Hopkins Hospital*, **13**, 29 (1902). Aldrich, T. B., "The active principle of the suprarenal gland," *Am. J. Physiol.*, **5**, 457 (1901); Takamine, J., "Isolation of the principle of the suprarenal gland," *J. Physiol.*, **27**, 29 (1901-2). For a review of the literature, see Grollman, A., "The adrenals," 1936.

²⁵⁴ The importance of the thyroid in metabolism was demonstrated about 1895 by Magnus-Levy. For the metabolic literature, see Du Bois, E. F., "Basal metabolism in health and disease." For the chemical aspects, see Kendall, E. C., "Thyroxine," New York, Reinhold Pub. Corp. 1929, and Harrington, C. R., "The thyroid gland, its chemistry and physiology," London, 1936. Kendall obtained an active principle of the thyroid in crystalline form in 1914. Harrington and Barger synthesized it in 1927.

²⁵⁵ Cannon, W. B., Shohl, A. T., and Wright, W. S., *Am. J. Physiol.*, **29**, 280 (1911-12); Cannon and Britton, S. W., *Id.*, **79**, 433 (1926-27); Cannon, "The wisdom of the body," New York, 1932; "Bodily changes in pain, hunger, fear and rage," Appleton, 1929.

charge of adrenaline into the circulation accelerates heart action, mobilizes glycogen, constricts blood vessels of skin and digestive system, thus making more blood available for muscles and nervous system. In the event that this mobilization for action is not followed by action, the mobilized sugar is excreted through the urine ("psychic glycosuria"). It was long known that fright (barking dog) induces glycosuria in the cat, and that attending exciting football games, or taking college examinations, is followed by sugar excretion²⁵⁶ (Sect. 10.8).

While the adrenal medulla (and adrenaline secretion) is highly responsive to the nervous system (to the medullary, hypothalamic, and spinal centers), the thyroid is relatively unresponsive. The thyroid function is of the long-range steady type, contrasted to the emergency-explosive type of nervous reaction of the adrenal medulla.

There may be associated with this relative functional difference between the adrenal and thyroid, a relative size difference. To quote from Robert Crile²⁵⁷, "the relative sizes of the adrenal and thyroid glands of animals might vary according to the energy characteristics and habits of the animals". The thyroid size in continuously sensitized man is about twice that of the adrenal size; the adrenal size in rodents, which rely on explosive outbursts of energy for survival, is about 23 times that of the thyroid.

C. Thyroid and anterior pituitary. As previously explained, the thyroid is under the control of pituitary thyrotropic hormone²⁵⁸ in the same manner that the gonads are under the control of pituitary gonadotropic hormone. Administration of the pituitary thyrotropic extract increases heat production (by action on thyroid) by 30 per cent²⁵⁹ to 60 per cent²⁶⁰. The thyrotropic hormone may be assayed by increase in heat production^{259, 260}, increase in size of the thyroid of the guinea pig²⁶¹, and/or the chick^{262, 263}. The anterior pituitary may also have a metabolism-accelerating principle which acts independently of the thyroid²⁶⁴, but this is not certain²⁶⁵.

The pituitary and thyroid hormones appear to be synergistic or complementary in their effects on growth and development²⁶⁶. The thyroid hormone "primes" or "tones" the tissues for the action of the pituitary growth hormones²⁶⁷. It appears, moreover, that sufficiently early thyroidectomy inactivates the pituitary so that the animal becomes virtually hypophysectomized as well as thyroidectomized²⁶⁸.

D. Thyroid and posterior pituitary. A curious observation²⁶⁹ relating the

thyroid to the posterior pituitary concerns a polyuria (diabetes insipidus) produced by placing a clip on the stalk of the pituitary. This polyuria is abolished by removing the thyroid, and returned by feeding thyroid to the animal (dog).

E. Thyroid and gonads. Thyroidectomy arrests sexual development (Fig. 7.5), and reduces energy metabolism; gonadectomy also reduces energy metabolism and reduces the thyroid. On the other hand, administration of sex hormone increases basal metabolism²⁷⁰. Puberty and pregnancy also enlarge the thyroid²⁷¹, perhaps by pituitary thyrotropic hormone stimulation²⁷².

As previously noted, the relation between thyroid and gonad is not fully clear, especially as it relates to rats. Lee²⁷³ reported that thyroidectomy of young rats did not seriously delay puberty but lengthened the estrus cycles. Hammett²⁷⁴, likewise, found no relation between thyroid activity and development of the reproductive system and suggested that the reported disturbed sex conditions are secondary to disturbed *general* growth, not to specific sex disturbance. But this depends on age of thyroidectomy. In our experience on cattle and goats early thyroidectomy arrests sex development completely. The discrepancies may be due to differences in physiologic age at thyroidectomy.

F. Thyroid and central nervous system. Attention has been called to the interrelation between "emergency" emotions, adrenal and thyroid, and to the influence of thyroid on nerve metabolism, on neuromuscular irritability and on variability. All this is, of course, equivalent to saying that there is an interrelation between thyroid, adrenal, and nervous system. By way of further evidence, one may note that the thyroid gland appears to be heavier in emotional than in non-emotional rats²⁷⁵, and that certain types of insanities ranging from "amazing placidity" and profound depression to high excitability, irritability, and anxieties are often improved by either thyroid administration or thyroid depression²⁷⁶. Ten per cent of the sufferers from dementia praecox are hypothyroid and most benefit from thyroid medication.

On the other hand, manic-depressive swings in mood in psychotic persons are often associated with swings in blood iodine²⁷⁷. In brief, while hypo- or hyperthyroidism is probably not the "cause" of psychotic conditions, it may

influence it, and the thyroid, in turn, may be influenced by the sensitiveness or instability of the nervous system.

It is of course obvious that cretinism includes arrested development of the central nervous system, that is, an arrested "mind", and this condition is often prevented by beginning thyroid medication at a sufficiently early age, provided of course the "residual physiologic capacity and latent growth potency of the neuroendocrine system"²⁷⁸ are adequate.

Many remarkable cases of psychiatric interest could be cited. One from Means²⁷⁹, concerns a mentally normal and unusually intelligent child of ten years who showed typical myxedema. On administration of thyroid which cured the myxedema, she developed a "mental decompensation", a severe manic-depressive psychosis. The psychosis disappeared on removing the thyroid medication but the myxedema returned. This result of benefiting one function and injuring another obviously has applications in agriculture as in medicine.

Then, too, according to Means, severe fright or worry may touch off a latent thyroid abnormality; for example, an exophthalmic goiter may develop in two or three days. Usually such development occurs gradually during a prolonged period of anxiety, sorrow, strife, or fear. The same may be touched off by acute infection, pregnancy, parturition, puberty, menopause, and other crises. On the other hand, many latent psychoses (manic depressive, acute delirium, toxic exhaustion, and so on) are brought on by toxic goiter²⁸⁰.

One could discuss the many theories of the influence of thyroid activity on human social leadership. But for our purpose the following is sufficient. Allee²⁸¹ observed that thyroid administration to hens at the highest "social level" caused loss in their "social order" in the flock if the thyroid caused them to moult. A lower thyroid dosage level did not affect their "social position", contrasted to the effect of raising birds in the social (aggressive) position following low dosages of testosterone propionate. The dosage level is very important in hormone effect.

What was said about the influence of the thyroid on the central nervous system could be said, if space permitted, about the adrenals and the other glands.

7.3.3: Some applications and summary of thyroid endocrinology. The thyroid resembles the pituitary in influencing all other endocrines. Pituitary control is by specific tropic hormones, but thyroid control is largely non-specific. The essential thyroid effect is, then, to accelerate the speed of all life processes, including those of the other endocrine glands and those of agricultural importance: milk production, egg production, and in some cases growth and reproduction.

The acceleration is not only for anabolic (building up) but also for catabolic (breaking down) and senescence processes. Thyroid administration can thus be practically helpful when the natural thyroxine production by the given animal is below the level required for optimal efficiency. Some individuals

and even species are slightly hypothyroid by nature; in such cases slight thyroid administration may be helpful. We have thus seen that the growth rate of some strains of mice and of some humans is accelerated by thyroid administration, but not that of the rats, guinea pigs, and rabbits investigated, nor of most humans.

Under certain conditions and at certain times (in the declining phase of the lactation period), the rate of milk production may be increased by thyroid administration at low levels. The question whether the milk-production efficiency (ratio of milk produced to feed consumed) is increased or decreased by the accelerated milk production has not yet been answered. Nor has it been determined how increasing the tempo of living by the thyroid administration affects the fertility and longevity of the animal, or its future usefulness. Under certain conditions the question of future usefulness does not enter; it is thus of little importance whether or not an animal's fertility or longevity is affected in the remote future by thyroid administration if it is planned to slaughter the animal in the near future.

7.4: Adrenal cortex. As outlined above, the adrenal gland consists of a medulla (central portion) which is associated with the sympathetic nervous system, and produces adrenaline; and a cortex (shell) which is associated with the reproductive system and produces some 20 steroids²⁸³ similar in structure to sex hormones (Fig. 7.1), collectively referred to as *cortin*²⁸⁴. Addison's disease (described by Thomas Addison in 1855) is due to atrophy of the adrenal cortex (usually by local tuberculosis). The adrenal cortex extract cortin or the steroids isolated therefrom (more recently synthesized) function successfully in replacement therapy when the adrenal cortex is removed or atrophied.

There is some functional relation between the adrenal cortex and adrenal medulla, in that cortin probably stimulates the sympathetic nervous system to conduct impulses to the medulla²⁸⁵, and that both are involved in carbohydrate metabolism²⁸⁶. Adrenaline is not physiologically essential for life maintenance (it appears to be useful only in emergency), but cortin is. Lack of cortin leads to profound hypoglycemia²⁸⁷, loss of sodium chloride²⁸⁷ and water, to potassium retention²⁸⁷, low blood pressure, weak heart action, reduced basal

²⁸⁷ In 100 cc blood from normal individuals, there are about 330 mg Na, 600 Cl, 19 K, and 85 sugar; blood from patients with Addison's disease contains about 250 mg Na, 450 Cl, 26 K, and 50-60 sugar.

metabolism (by about 25 per cent), disturbed temperature regulation, and general muscular weakness. The two most obvious adrenal-cortex functions are, then, salt and water balance²⁸⁸ and maintenance of the blood sugar level by gluconeogenesis²⁸⁹ (sugar formation from protein). Two adrenal-cortex steroids, 11-dehydrocorticosterone and 17-hydrocorticosterone, are apparently involved in both salt and blood-sugar regulation. The particularly potent salt-regulating steroid is desocorticosterone²⁸⁸ and the particularly potent carbohydrate former is corticosterone²⁸⁹. Both of these steroids were isolated and synthesized (1937) by Reichstein (Zurich), but Kendall and Mason and Wintersteiner and Pfaffner (U. S. A.) made outstanding chemical contributions and elucidated the relations between the many steroids.

The sugar-forming potency of corticosterone (and to a less extent of 11-dehydrocorticosterone and 11-dehydro-17-hydrocorticosterone) is great enough to induce severe glucosuria²⁹⁰ on its administration.

In the absence of cortin or its active steroids, life may be maintained in Addison's disease (or adrenalectomy) by increasing the intake of sodium salt, the amount depending on the condition (edema, etc.) and reducing intake of potassium salt; to overcome the tendency to hypoglycemia, and consequent muscular weakness, increase the carbohydrate intake. Hartman outlined methods for measuring cortin deficiency and emphasized the extra cortin demands in conditions of stress, "infections, toxins, shock, great heat, great cold, exercise"²⁹¹.

The fact that extra cortin is needed under conditions of stress does not mean that it would benefit normal animals to have extra cortin. Indeed, as in the case of thyroxine, the opposite may be true, depending on dosage and sensitivity of the animal. As on administration of excess thyroxine or thyrotropic hormone, so on administration of excess cortin or adrenotropic hormone there is increase in the catabolic rate, especially of protein deamination and urinary nitrogen excretion. The excessive deamination is associated with excess sugar formation and excretion. The effect on nitrogen metabolism and on growth is opposite to that of pituitary growth-hormone administration²⁹² (which increases protein anabolism and reduces nitrogen excretion). There appears to be a reciprocal relation of the pituitary-growth and adrenal-cortical hormones in their effect on protein metabolism^{292, 293}.

It is interesting to note (Fig. 17.5) that on approaching maturity, when the rate of total body gain declines rapidly, the rate of weight gain of the adrenal cortex increases

²⁸⁸ Loeb, R., *Science*, **76**, 420 (1932); *J. Exp. Med.*, **57**, 775 (1933). Thorn, G. W., *et al.*, *Id.*, **94**, 348 (1941).

²⁹¹ Hartman, F. A.²⁸⁶ There is a large literature on shock. For a review, see Rubin, S. H., *et al.*, Macy Foundation, 1941. Schleser, I. H., and Asher, R., *Am. J. Physiol.*, **183**, 1 (1942). Swingle, W. W., *et al.*, *Am. J. Physiol.*, **139**, 481 (1943).

²⁹² For review of the literature, see Tepperman, *et al.*, *Endocr.*, **32**, 373 (1943), and Long²⁸⁶.

²⁹³ Long, C.N.H., *Cold Spring Harbor Symposia on Quantitative Biology*, **10**, 98 (1942). Marx, W., Simpson, M. E., *et al.*, *Endocrinology*, **33**, 102 (1943).

rapidly until total weight gain is brought to a standstill. The adrenal cortex activity may be the limiting factor in bringing growth to a standstill (C. W. Turner). Would removing part of the adrenal cortex permit further growth? The adrenal-cortex spurt in growth coincides with the gonad spurt in growth, and the sex hormones, at any rate estrogen, are known to depress the growth-promoting properties of the anterior pituitary²⁹⁴; dwarfing of rats and chickens was produced by administration of follicular hormone²⁹⁴. Corticosterone (not desocorticosterone) is particularly effective in repressing lymphoid tissue²⁹⁵ (thymus, lymph nodes). Corticosterone or cortin administration, of course, atrophies the adrenal cortex by repressing liberation of corticotropic hormone²⁹⁶. Under stress adrenotropic hormone output is increased and the adrenal is hypertrophied. The level of cortin metabolism apparently parallels that of basal metabolism.

Just as the basal metabolism per unit weight is greater in small than in large animals (Chs. 13 to 15), so is the cortin need per unit weight. A rat needs 40 times and a cat 4 times as much cortin per unit body weight as man (Hartman). The importance of the adrenal-cortical function in metabolism is indicated by hypertrophy of one adrenal if the other is removed, and the fact that such hypertrophy is avoided by administration of adrenal-cortical extract. Also, newly-born of adrenalectomized mothers show abnormally large adrenals²⁹⁷.

As previously explained, sex hormones and adrenal-cortex hormones are related structurally (Fig. 7.1) and functionally. Gonad removal hypertrophies the adrenal cortex²⁹⁸, while sex-hormone administration reduces the adrenal cortex. Progesterone is said to atrophy the adrenal cortex of male rats²⁹⁹, although this problem is still under investigation. Estrogen, however, is said to have the opposite effect—adrenal hypertrophy—and therefore increase in protein catabolism and suppression of growth. The “infant Hercules” type of precocious sexual and muscular development is associated with adrenal-cortex tumor; so is virilism in women³⁰⁰ (the circus’ “bearded lady”); and perhaps some types of feminism in men may be attributed to adrenal-cortex dysfunction. Conversely³⁰¹, sex hormones, or hormone-like bodies, particularly progesterone and stilbestrol, may substitute for some adrenal-cortex hormones by causing sodium-ion retention and potassium-ion excretion.

Riddle³⁰² reported that adult pigeons and doves “showed male behavior to an extent equalling that of any normal bird that I have ever observed”, yet “these birds never possessed a gonad”. The male behavior of these gonad-

less birds is attributed to adrenal-cortical male hormone production, said to be produced by a special *androgenic tissue*, associated with the adrenal cortex. Pseudo-male hermaphroditism with male behavior and functional prostatic tissue in the absence of testicular tissue is attributed to androgen production by this androgenic adrenal tissue³⁰³.

Not only sex hormone but also lactation hormone (cortilactin) was prepared (by isoelectric precipitation) from the adrenal cortex³⁰⁴. This stimulates the crop sac of pigeons similar to (pituitary) prolactin (Sect. 7.2).

Richter³⁰⁵ called attention to the influence of adrenalectomy on appetite behavior (Chs. 10 and 20). Removal of the adrenals is followed by excessive loss of sodium chloride and also by a compensating appetite for salt. A boy who had excessive craving for salt was found to have an adrenal cortex eroded by a tumor. Conversely, adrenal (and other) abnormality may often be inferred from observation of the appetite.

Glutathione is said to be involved in growth acceleration (Chs. 6 and 16), and it may be significant that adrenal tissue is richest in glutathione³⁰⁶.

As noted in the introduction, the adrenal cortex is interrelated with the anterior pituitary adrenocorticotrophic hormone, with the pituitary occupying the "controlling" position. This is indicated by adrenal cortex atrophy on pituitary removal (the atrophy is greater than could be caused by thyroid deficiency), and adrenal restoration to normal on pituitary implantation³⁰⁷. The effect on the microscopic picture of the adrenal medulla appears within 2 hours after the pituitary administration³⁰⁸. Under some conditions A.P. administration may depress the catabolic effect of the adrenal cortex (and thus accelerate growth)³⁰⁹. Under other conditions A.P. administration may lead to adrenal hypertrophy (70-130%)³¹⁰; conversely, adrenalectomy or adrenal administration affects the pituitary³¹¹. Preparation of pituitary adrenotropic hormone was recently reported³¹².

In addition to the interrelation of the adrenal cortex to the pituitary and gonads, it is also related to other endocrines, such as the thyroid. Hyperthyroidism leads to hypertrophy of the adrenal cortex³¹³, perhaps as a result of increased metabolism. Apparently anything that increases metabolism (including lactation) hypertrophies the adrenal cortex. Then, too, it is said that the adrenal cortex exercises an inhibiting control over the thyroid³¹⁴. Individuals with hypofunctioning adrenals are particularly sensitive to thyroxine, leading to "hyperthyroid crisis"³¹⁵ on thyroid administration.

Summarizing, the adrenal cortex produces hormones similar to sex hormones. It is especially associated with the regulation of salt and water metabolism and with carbohydrate and protein metabolism, and therefore with growth, lactation, and related productive processes. Because of its effect on carbohydrate metabolism, especially gluconeogenesis, the adrenal cortex function may, perhaps, be a limiting factor in milk production. Relative hypofunction of the adrenal cortex in comparatively high-milking animals may, perhaps, lead to the hypoglycemic type of milk fever. On the other hand, hyperfunction of the adrenal cortex may cause inefficient feed utilization and growth depression. The field is at present under intensive investigation, the results of which explain many phenomena, and find use in medicine; but they have not yet been carried to the point of application in agriculture.

7.5: Calcium-phosphorus metabolism hormones: the parathyroids³¹⁶.—As previously noted, all hormones are metabolic catalysts, but some, like the thyroids, are best known for their catalytic effect on energy metabolism, although the effect is no less apparent on calcium metabolism³¹⁷. The gonads are best known for their effect on sex activity, although they, too, catalyze calcium metabolism, which is certainly true as regards the effect of estrogen on calcium storage, on blood calcium in birds³¹⁸, and on bone metabolism and strength³¹⁹. On the other hand, ovariectomy often leads to hypocalcemia³²⁰. The adrenal cortex is best known for its effect on energy and carbohydrate metabolism and on maintenance of muscular efficiency, although it has an equal effect on sodium retention and on electrolyte balance. Likewise, the parathyroids (Fig. 17.30) are best known for their effect on calcium and phosphorus metabolism; by controlling this, they may be said to regulate growth and related productive processes³²¹.

The word "control" (of calcium metabolism) is perhaps too strong for characterizing the parathyroid effect on calcium metabolism; "regulation" is better. Just as adrenalectomized animals may be maintained under quiet conditions by administration of extra salt, water, and carbohydrate, so parathyroidectomized animals under quiescent conditions (not pregnant or lactating) may be maintained by administration of extra calcium and vitamin D.

Calcium occupies an extremely important position in the body economy in

general, and in growth, milk and egg production in particular. About 2 per cent of the body is calcium and 99 per cent of this calcium is in the skeleton³²². While support is one of its obvious functions, the skeleton is not merely an inert supporting structure. The skeleton is, on the contrary, like other constituents of the living body, in rapid flux³²³. The calcium in bone is interrelated with the calcium-ion level in the blood, as body glycogen is interrelated with the glucose level in the blood (Sects. 10.4 and .5).

The calcium-ion level in the blood is the resultant of dietary calcium and vitamin D, calcium outgo (into bone, milk, egg, etc.), and parathyroid hormone level (Ch. 20).

Normally, the blood serum or plasma contains about 10 mg per cent of calcium (in whole blood about 5 mg per cent) half of which—about 5 mg per cent—is in the form of calcium ion and the other half as calcium proteinate. On parathyroid removal, the blood-serum calcium declines to about half normal (5 mg per cent) and the organic phosphorus rises to about 25 per cent above normal (from about 5 to about 7.5 mg per cent). On injecting parathormone (or on overactivity of the parathyroid, usually due to tumor) the opposite occurs—the blood calcium level may be doubled and the organic phosphorus level may be halved. The quantitative effect is analogous to that of thyroid removal and thyroid administration.

The detailed mechanisms whereby these changes are brought about are at present under investigation. Unlike the thyroid, the parathyroid does not appear to be under pituitary control³²⁴. In addition to the calcium mobilization from bone, parathormone, like cortin, may exert an effect on selective kidney function.

The calcium factor is particularly important in the dairy industry not only because calcium is one of the most valuable dietary constituents in milk, but also because it is often a limiting factor in milk production. The blood-calcium level in high-milking cows may decline to very low levels with the resulting dangerous "milk fever" (just as the blood-sugar level may decline to abnormally low level in adrenal hypofunction or in low carbohydrate intake, causing "milk fever"). Under such or similar conditions, when the calcium outgo into the milk greatly exceeds the income from feed, the parathyroid is hypertrophied in the performance of its function of mobilizing the bone calcium³²⁵. But in spite of the hypertrophy, the blood calcium may decline during heavy lactation and, in some species, during the later phases of gestation. The low blood calcium in milk fever is probably not the result

³²² *Composition of bone*: 60 per cent is ash; of the bone ash, 80 per cent is $\text{Ca}_3(\text{PO}_4)_2$, 13 per cent is CaCO_3 , 2 per cent is $\text{Mg}_3(\text{PO}_4)_2$; or 36 per cent of the ash is Ca, 16 per cent is P; 0.5 per cent is Mg, and 5.5 per cent is CO_2 . It turns out that the Ca to P ratio is about 2 to 1, and that the $\text{Ca}_3(\text{PO}_4)_2$ to CaCO_3 ratio is about 1 to 1.5.

of low dietary calcium, out of the inability of the digestive, assimilatory and calcium-mobilizing mechanisms to keep up with the milk-secreting mechanisms.

While dairymen would like to develop a more efficient parathyroid in cattle, or a parathyroid hormone suitable for administration to cattle to avoid milk fever, the cure might be worse than the remedy. Increasing the parathyroid efficiency might weaken the bones and deteriorate the teeth. The organismic-homeostatic viewpoint does not encourage parathyroid hormone administration to normal animals just as, as a rule, it does not encourage the administration of other hormones unless the animal is particularly deficient in some one hormone as contrasted to the abundance of other factors.

Fortunately, as previously noted, the calcium-ion level in the blood is a function not only of the parathyroid-hormone level but also of calcium and vitamin D intake in proper form³²⁶. The purely practical problem of avoiding milk fever, therefore, seems to be nutritional—supplying a high level of dietary calcium in proper form and vitamin D (irradiated yeast now available in inexpensive form)³²⁷. It appears³²⁸ that milk fever in dairy cattle is decreased by feeding them a million I.U. units vitamin D (irradiated yeast) 30 days before and 10 days after calving.

The overall parathyroid function is to maintain constant the calcium-ion level in the blood serum, if necessary by removing the calcium from bones. By decalcification of bone under adverse conditions of dietary calcium supply, excess parathyroid aggravates rachitic processes. Hyperparathyroidism causes serious bone disease. Vitamin D, on the other hand, promotes calcium deposition into the bone, if necessary by lowering the blood calcium. In brief, while the primary function of the parathyroid hormone is to maintain constant the calcium level in blood, that of vitamin D is to deposit calcium in the skeleton, which necessitates its removal from the blood. The two processes are balanced in a normal well-fed animal. The effect is opposite on serum phosphorus: parathyroid hormone depresses the serum phosphorus, vitamin D raises it.

While under conditions of dietary calcium deficiency vitamin D may, theoretically, reduce the blood calcium level by building it into bone, it ordinarily has a calcemic effect; it increases the blood calcium level by increasing the calcium absorption from the digestive tract. Indeed, in case of parathyroid deficiency, vitamin D₃ (7-dehydrocholesterol, from fish livers), vitamin D₂ (calciferol, an activated ergosterol) and dihydrotachesterol ("A.T.10", also an activated ergosterol derivative) tend to maintain the blood calcium at a normal level³²⁹. A.T. 10 increases the blood calcium level but, unlike vitamin D, is not antirachitic.

The obvious prophylactic against hypocalcemic milk fever and rickets seems to be to

³²⁹ McLean³²⁶. "There is a species difference in the calcemic effects of the 3 substances. Thus vitamin D₃ is equivalent to 40,000 U.S.P. units/mg for both rat and chicken; but while vitamin D₂ is equivalent to 40,000 units/mg in the rat, it is only 1000 units/mg in the chicken; crystalline dihydrotachysterol is equivalent to 80 U.S.P. units in the rat and 360 in the chicken. In the chick vitamin D₂ is 35 times as effective as vitamin D₃ and dihydrotachysterol is 4.5 times as effective as vitamin D₃." E. W. McChesney, *J. Nut.*, **26**, 81 (1943).

feed a high level of calcium in available form and irradiated yeast which, incidentally, also increases the vitamin D level in milk.

The growth of knowledge of the anatomy of the parathyroids paralleled that of the thyroids, beginning with about 1880 (Sandstrom). The relation of the parathyroids to nervous symptoms has been known since about 1890 (Horsley, Gley, Kohn), although it was not until 1908 that McCallum and Voegtlin³³⁰ discovered that parathyroid removal in dogs is followed by abnormally low blood calcium and by "twitching, rigidity, tachypnoea, fibrillary tremors, increased rapidity of the heart beat, etc.", all of which are overcome by intravenous injection of a 5 per cent solution of calcium acetate or lactate.

This definitely established the fact that the parathyroids regulate calcium metabolism. By 1925 potent parathyroid extracts had been prepared, especially by Collip³³¹, which substituted for the parathyroid in parathyroidectomized animals and caused hypercalcemia in normal animals³³².

Much incidental information gradually accumulated, such as that the decline in blood calcium is associated with an increase in blood phosphorus³³³ (there tends to be a constant product of calcium and phosphate ions; the Ca/P ratio tends to be between 1 and 2, so that the proper functioning of the calcium metabolism is also dependent on a certain phosphate concentration³³⁴); that meat³³⁵ aggravates and milk (or lactose³³⁶) helps in maintaining parathyroidectomized animals. At the same time the nutritional literature³³⁷, as well as the hormonal, indicates that lactose ingestion exerts favorable influence on calcium assimilation, as does a proper Ca/P ratio. Anything that decreases the solubility of calcium salts (as excess oxalates, phosphates, alkalinity) decreases calcium absorption.

The importance of ionic balance ("ionic antagonism") on neuro-muscular irritability and permeability, especially in relation to calcium ions, has been long known³³⁸, and also its widespread influence as, for example, on blood clotting, milk clotting, digestion, and so on. The same is true as regards phosphorus, which is not only a part of bone and every cell but is important in intermediate metabolism (phosphorylation, see Ch. 6). The same substance, calcium or phosphorus, seems to be used for many different purposes in the body and deficiency exerts correspondingly widespread effects.

7.6: Carbohydrate-fat metabolism hormones³³⁹. There is a similarity of pattern in the anatomy, physiology, and even in the history of our knowledge of the various endocrines and hormones and their interrelations.

As regards the carbohydrate-metabolism hormone insulin, we have first the discovery of the relation of the disease diabetes to an organic lesion of the pancreas; second, duplication of the disease by removal of the pancreas³³⁹ (Mering and Minkowski, 1899); third, the correlation of the disease with special structures in the pancreas, the islets of Langerhans (Opie, 1901); fourth, the idea of the presence of a hormone (M.W. 35000, named "insulin" by Shaffer in 1916); fifth, the search for and discovery of the hormone. Several groups of workers independently prepared active extracts, but one³⁴⁰ carried the work to the stage of successful substitution therapy in man.

There is likewise a parallelism between the regulatory effect of insulin on blood sugar and, for example, of parathormone on blood calcium. Bone is the bodily reservoir for blood calcium, and glycogen is the bodily reservoir for blood glucose (Sects. 10.4 and 10.5).

Insulin has at least three interrelated functions: (1) the homeostatic one (Sect. 10.4) of maintaining constant the glucose level in the blood by shifting the reaction $\text{glycogen} \rightleftharpoons \text{glucose}$ to the right or left; (2) storing glycogen in the liver and muscle; (3) catalyzing the oxidation of carbohydrate.

A more recent development is that the anterior lobe of the pituitary has an insulin-antagonizing hormone, the so-called diabetogenic or glycotropic factor³⁴¹. Houssay³⁴¹ reported that an animal made diabetic by removal of the pancreas is improved with regard to diabetic symptoms (high sugar and ketone bodies in blood and urine) and lives longer if the anterior lobe of the pituitary is likewise removed. Such an animal (depancreatized and hypophysectomized) is called a "Houssay animal". It is, of course, very remarkable that an injury to two organs is more favorable than to one, and this fact emphasized dramatically the concept of balance. Young³⁴² confirmed the observations that hypophysectomy decreases diabetic intensity in diabetic animals, and he further observed that administration of A.P. extract to normal animals may lead to severe, permanent, diabetes. The effect is apparently by way of the islets of Langerhans, first overstimulated, than destroyed³⁴³. Diabetes may thus result from pituitary overactivity as well as from pancreatic underactivity.

It is important to note that removal of the adrenals in diabetic animals likewise improves the diabetic condition³⁴⁴. The adrenalectomy effect is observed only in the presence of the pituitary, indicating that the pituitary hormone acts through the intermediacy of the adrenals. This has been adequately confirmed.

The problem of endocrine balance and its relation to *ketosis* is so important

in practice that it is desirable to outline it. First is the fact that in their metabolic history fatty acids apparently pass through a ketone stage, most conspicuously acetoacetic acid, $\text{CH}_3 \cdot \text{CO} \cdot \text{CH}_2 \cdot \text{COOH}$. But the "ketone bodies" also include beta-hydroxybutyric acid, $\text{CH}_3 \cdot \text{CHOH} \cdot \text{CH}_2 \cdot \text{COOH}$, and acetone, $\text{CH}_3 \cdot \text{CO} \cdot \text{CH}_3$. The overall reaction leading from, say, palmitin or palmitic acid to a ketone may be illustrated in several ways, for example, by the reaction

The accumulation of ketone bodies in diabetes used to be explained³⁴⁵ by assuming that their oxidation involved a coupling with carbohydrate, that one molecule of glucose is needed to burn "smokelessly" one to two molecules of fatty acid, and that ketone bodies form in the absence of sufficient glucose.

The current idea seems to be³⁴⁶ that carbohydrates are not antiketogenic in Shaffer's coupled-reaction sense but, more simply, in the sense that when the carbohydrate oxidation is low, fat oxidation is correspondingly high, and relatively high fat metabolism necessarily involves relatively high ketone formation. The fat metabolism is high when carbohydrate cannot be utilized, as in diabetes, during starvation (either total or specific carbohydrate starvation), when oxidation is confined to fat, following the administration of anterior pituitary "diabetogenic hormone"³⁴⁷. This is assumed to mobilize fat from the fat depots, causing hyperlipemia and fatty infiltration of the liver, which liver fat replaces the liver glycogen (the effects of both insulin and the pituitary diabetogenic hormone are on the liver—neither is effective in liverless animals³⁴⁸), and the metabolism is largely of fats. Insulin and available carbohydrate prevent ketosis by inhibiting fat infiltration into the liver and storing glycogen instead; the anterior diabetogenic factor, on the contrary, stimulates hyperlipemia and fat infiltration into the liver, with consequent high fat metabolism and therefore ketosis. It is possible that low blood sugar, or low dietary carbohydrate, stimulates the pituitary to produce the diabetogenic factor.

Ketosis is of considerable agricultural importance. Ketosis, like a certain type of milk fever caused by low blood sugar³⁴⁹ (as well as by low blood cal-

cium, discussed in the parathyroid section), is fairly common in high-producing ruminants in late winter and early spring³⁵⁰. The explanation may be, roughly, as follows³⁵¹: (1) the soluble carbohydrates have been fermented and leached from the hay and silage by late winter and early spring; (2) great quantities of fatty acids are formed by fermentation in the rumen³⁵², especially if the fodder is low in soluble carbohydrate, and absorbed; (3) lactation (and gestation) makes great demands on the soluble carbohydrates. The result of the low glycogen reserve is high fat reserve in the liver with ketone formation as explained above. The remedy is, obviously, feeding good roughage (containing high levels of soluble carbohydrate) and, if necessary, such feeds as molasses, up to two pounds a day (to lactating dairy cows).

Duncan, Huffman and Tobin reported that the acetone-body concentration in their cows suffering from ketosis was 23 mg per cent in the blood and 155 mg per cent in the urine. Following recovery, the concentration was, respectively, 3 and 54 mg per cent in the blood and urine. Manifestations of ketosis in cattle (depression or excitement, decline in milk production and feed consumption, depraved appetite, stiffness) are said to begin when the ketone bodies exceed, respectively, 10 and 20 mg per cent in the blood and urine.

Summarizing, this section presents a diagrammatic outline of one aspect of the hormonal regulation of carbohydrate and fat (ketosis) metabolism, with notes on their relation to the nature of the food supply. Other neuro-endocrine factors influencing metabolism were discussed in the thyroid and adrenal sections. Non-hormonal catalysts, including choline, influencing especially fat metabolism, are discussed in Chapters 6 and 20.

7.7: Anterior-pituitary and growth hormones. The removal of the anterior-pituitary (A.P.) in growing animals not only stops growth but leads to marked loss in body weight³⁵³. Growth is resumed at the normal or even at supernormal levels on *injecting* (but *not ingesting*, except possibly in some amphibians) A.P. extract³⁵⁴, or simply by daily implantation of pituitary tissue³⁵⁵.

On the other hand, A.P. injection or implantation into normal animals leads in young animals to gigantism^{354, 356} and in some species of adult animals

(dogs, but not rats) to acromegaly. In both there is marked visceromegaly³⁵⁶, increased size of chest, thickening of skin and increased hair growth. The effects on different organs varies with the species. Splanchnomegaly has been noted in acromegalic humans and dogs and splanchnomegaly in pituitary dwarfism. The spleen is hypertrophied to double the normal size due to hyperplasia of the reticular and endothelial cells of the red pulp³⁵⁷ and hypertrophy of the liver by true hyperplasia³⁵⁸.

The female rats administered pituitary growth hormone by Evans attained 700 grams as compared to 300-gram litter mates; and male rats reached 900 grams compared to 450-gram litter mates. The successive growth increments in the rats decreased with successive hormone increments until further hormone additions were without effect. Forces other than epiphyseal closure operate to limit growth.

This upper limit may, perhaps, be reached without hormone administration by dietary means alone. Thus the Anderson-Smith fed rats³⁵⁹ weighed 300 grams at 63 days, more than the hormone-treated rats of Evans and Long³⁶⁰ that weighed 228 grams at 75 days. The Anderson-Smith fed rats weighed 500 grams at 123 days, close to the hormone-treated rats of Evans and Simpson³⁶¹ that weighed 500 grams at 125 days. There may, however, have been genetic size differences between the Evans and the Anderson-Smith rats, so that these two groups of rats may not have been comparable.

There is a large literature on pituitary gigantism associated with pituitary tumors³⁶², and on dwarfism associated with defective pituitary inheritance³⁶³ or hypophysectomy³⁶⁴.

These observations indicate that the pituitary has a major function in growth and development. One problem at present under investigation is whether this pituitary control is (1) *direct* on the growing tissue, by means of specific growth or somatotrophic hormone(s), or (2) *indirect* by way of pituitary trophic or tropic hormones, which act as "triggers" on other "target" endocrines, exemplified by action of the pituitary thyrotrophic hormone on the

thyroid, which in turn controls growth aspects (Fig. 7.3). It is evidently a difficult, if not impossible, task to separate these two different types of controls.

The following recent data³⁶⁶ on the growth of a human giant are instructive on what a pituitary abnormality may lead to. The parents, brothers, and sisters were normal (Fig. 7.6).

Age (years)	Weight (lbs)	Height (feet) (inches)
Birth	8½	
½	30	
9	178	6-0
11		6-7
14		7-5
19	435	8-6
21 ³⁶⁶	495	8-8
22	491	8-9½
(died from infection of foot)		

The literature reports taller men (cf. Biblical 9 ft 9 in for Goliath, 9 ft 9 in for an Arabian giant reported by the Roman Pliny, etc.), but Dr. Humbred believes that this man, less than 9 feet, is the tallest on record, representing the genetic ceiling.

Though large, these giants are weak. Thus injection of A.P.E. enlarges the liver, but the enlargement is often associated with a central atrophy or necrosis³⁶⁷. Similar results of external enlargement and internal degeneration were reported on bone growth in guinea pigs and mice³⁶⁸.

The medical literature is concerned with the use of growth-hormone preparations on various types of dwarfs. Dwarfism is commonly divided into: (1) anterior hypopituitarism; (2) primary anterior pituitary and secondary thyroid deficiency; (3) primary thyroid and secondary anterior pituitary deficiency. Uncomplicated hypopituitarism (normal except hypofunction of the eosinophil cells) is associated with small size but normal proportions; hypothyroidism is associated with abnormal bodily proportions and maldifferentiation. The thyroid and pituitary—as well as many other endocrines—act synergistically. The therapeutic hormone preparation necessarily varies with the cause and nature of the dwarfism. The pituitary dwarf, whose bodily proportions, texture of skin and hair, and mental development are normal, although often sexually undeveloped, is treated with the "pituitary growth" preparation. The thyroid dwarf, whose bodily proportions, texture of skin and hair and mental development are abnormal, is treated with thyroid. Because of the synergistic interrelations of pituitary and thyroid hormone, both are often employed together. Certain types of bone-growth dwarfisms may be associated with defective adrenals. It has been reported³⁶⁹ (but not confirmed) that adrenalectomy results in a stunting of bone growth similar to that of hypophysectomy. Whichever the mechanism of action of the pituitary on growth, it is undoubtedly indispensable during postnatal growth and development.

But in early prenatal life, prior to the development of the functional pituitary and

³⁶⁹ Ingalls, T. H., and Hayes, D. R., *Endocr.*, **29**, 720 (1941).

the other endocrines³⁷⁰, the chick embryo for example, seems to be doing well enough without the pituitary and at ages when growth and development are most rapid. Does the egg contain all the hormones? Are these growth-development catalysts needed in later life only to overcome some back pressure, some "resistance"; or are the hormones needed to "detoxify" something that develops with increasing age?

Primitive organisms do not have this elaborate net-work of endocrines. Indeed, it is said that early removal of the anterior pituitary in so highly evolved an organism as the axolotl salamander does not interfere with growth³⁷¹. Time, and stage of maturity, both individual and racial, seem to be decisive factors in the production and action of endocrines³⁷². Increasing involvement of ever more complex integrating devices—neuro-endocrine systems—is a conspicuous feature of organic evolution, both individual and racial. Simple cell division under simple nutritive conditions does not appear to require a pituitary or other endocrine.

Fig. 7.6—Comparative growth of normal and giant boys. The values of the exponent in the equation indicates the relative (or percentage when multiplied by 100) growth rates. Thus prior to age 9 or 10 years the giant grew at 20.9% while the normal boy grew at 10.9% per year (for elucidation of growth rate see Ch. 16).

The investigational difficulties are complicated by racial as well as species differences. Thus different dove races vary in their thyroid size³⁷³ and in pituitary lactogenic hormone (prolactin) concentration³⁷⁴. Differences in lactogenic hormone concentration were also observed between beef and dairy cattle³⁷⁵, goats³⁷⁶, rats³⁷⁷, mice³⁷⁸, and

dogs³⁷⁹, ³⁸⁰ at various ages and periods of gestation and lactation (lactogenic hormone per mg pituitary is about 0.01 I.U. in non-lactating and about 0.05 I.U. in lactating mice, rats, and rabbits).

The analytic difficulties are further multiplied by differences in interrelations and synergisms in different species. Thus the thyrotropic and lactogenic hormones are synergistic and mutually supplementary in their effects on growth in dwarf mice³⁸¹ and in heat production in pigeons³⁸², and so on.

The above discussion does not answer the question as to whether or not there is anterior-pituitary hormone acting *directly* on body growth (independently of other target glands), as is believed by Evans. General agreement will probably be delayed until (1) the pure A.P. growth hormone (if such is present) is obtained, and (2) it is demonstrated that it does not act on other endocrines, or that it stimulates growth in the absence of other endocrines or hormones—perhaps an impossible demonstration since growth is an overall process, the resultant of innumerable interrelated factors. It therefore seems most logical to assume that growth is a function of many hormones, not of one specific growth hormone.

The most interesting agricultural feature of the claimed effect of A.P. "growth hormone" injection in young animals is the increase in growth rate and ultimate body size in general and protein retention in particular. The ultimate body size following A.P. "growth hormone" injection is apparently not larger than can be obtained by proper dietary means³⁸³. The important claim, somewhat difficult to accept, is that on a *given* quantity of the same food (when the animals are said to be "pair fed", see Ch. 20) animals treated with A.P. extract grow faster in weight³⁸⁴.

Lee³⁸⁴ reported data on four groups of rats: (1) one was analyzed at the beginning of the experiment; (2) another served as control; (3) a third was treated daily with 3 rat units of pituitary growth extract, and was restricted in food consumption to the same amount as that voluntarily eaten by its control mate; (4) a fourth was likewise treated with growth extract but was allowed food *ad libitum*.

Lee's data indicate that (A) the treated animals on the *ad libitum* diet consumed 10 to 15 per cent more food than the non-treated controls; (B) the treated animals gained more weight than the untreated even if pair-fed (consuming the same amount of feed as the controls); (C) the heat production per unit area was the same in the treated and non-treated animals. The apparent conclusion is that growth hormone not only in-

³⁸⁴ Lee, M. Q., *Proc. Assn. Res. Nerv. Mental Dis.*, **17**, 193 (1936), based on: Lee and Schafer, N. K., *J. Nut.*, **7**, 337 (1934); *J. Biol. Chem.*, **108**, 355 (1935). Lee and Ayres, G. B., *Endocrinology*, **20**, 489 (1936). Marx, W., *et al.*, *Am. J. Physiol.*, **135**, 614 (1942).

creases food consumption, but also increases weight gains, even if the food consumption is not increased.

Lee's results, illustrated by Fig. 7.7a, b seem puzzling, because the hormone-injected rats gained more weight than the controls in spite of the fact that (a) they consumed no more food than the controls; (b) they must have had a higher maintenance expense than the controls because they were larger; (c) they probably had a higher maintenance expense because, being restricted to the food intake of the smaller animals, they were probably hungrier and more restless.

How should one explain in the face of the second law of thermodynamics (Ch. 2) the greater weight gain of the hormone-treated animals on the same energy intake as the controls? One possibility is that the differences in weight gain are due mostly to differences in water, with proportionally greater protein and mineral storage (the caloric value of 1 g of fat gain is equivalent to 8 g of non-fat gain). This idea that the weight gain represents not energy but largely water is substantiated by the following tabulation (last column by the writer) of Lee's data.

	Gain in empty carcass, weight (g)	Gains in empty carcass (g) in the form of:				Estimated Cal in carcass, assuming 5.7 Cal/g protein and 9.4 Cal/g fat
		Water	Fat	Protein	Ash	
12 controls	716	324	281	96	22.7	3189
12 treated	1217	771	162	237	45.1	2874

The stored energy in the treated rats is seen to be less than in the untreated smaller rats. The larger size of the treated animals is due mostly (about 90 per cent) to water gain, with corresponding gain in protein and ash (ratio water to protein is about 3.3 in both groups; ratio of water to ash is about 14 in the control and about 17 in the treated animals). This result is somewhat similar to that on growth-acceleration of mice by thyroid administration; the gains were due not to total energy but to extra water, protein, and mineral storage.

Lee interpreted the greater water, protein, and ash content of the treated rats as due to their chemical immaturity³⁸⁵ in the sense that "the increment of body material during active growth is itself also characterized by a relatively high content of water, protein, and salts and low content of fat". Lee also investigated the changes in body weight and body composition of normal and hypophysectomized rats pair-fed 33 days (Fig. 7.8B). In spite of the same energy consumption, the hypophysectomized rats lost weight much more rapidly than the controls.

This impermanency of the gains in the A.P.-injected animal was termed by Lee "lability of growth effect", and is interpreted by him as due to storage of the labile "deposit protein"³⁸⁶. "In some cases . . . control animals overtake and pass their erstwhile treated mates". Lee's interpretation that A.P. growth-hormone injection accelerates true growth is substantiated by Brues'³⁸⁷ data on more rapid liver regeneration after partial hepatectomy in hormone-injected than in (pair-fed) control rats. The increase in size was due to true hyperplasia³⁸⁸ of all liver components in the same proportions as they existed initially. The liver in the injected rats contained more water, ash, and protein than in the control rats. All visceral organs grew more rapidly

³⁸⁵ Moulton, C. R., *J. Biol. Chem.*, **57**, 79 (1923). The mammalian embryo contains 70 to 100 times as much water as nitrogen; the mature animal contains about 20 times as much water as nitrogen.

following hormone injection than the body as a whole. Thus in dogs made acromegalic by A. P. growth extracts, the ratio $\frac{\text{weight hormone-treated animals}}{\text{weight control animals}}$ was reported³⁸⁹ to be 1.87 for the body as a whole; 2.2, heart; 3.36, lungs; 3.42, liver; 1.16, spleen; 2.67, pancreas; 2.43 kidneys. The glomeruli and tubules of the kidneys were greatly enlarged, and subcutaneous and omental fat decreased.

The A. P. Growth extract stimulates the activity of the periosteal ossification zones³⁹⁰ without the benefit of increased phosphatase activity³⁹¹. However, as previously noted, the larger size may be associated with internal degeneration.

Summarizing, the anterior-pituitary occupies the highest position in the endocrine order of growth regulators. However, the pituitary does not seem to be essential in early embryonic growth, and it may even be removed in some lower forms, for example, amphibian larvae, without inhibiting growth. Moreover, growth continues for a considerable time even after the pituitary is removed. At later ages, however, the pituitary appears to be indispensable for growth and even for maintenance of mammals. This result is not surprising since, as explained in Sect. 7.1, removal of the pituitary leads to atrophy of many of the major endocrines, such as thyroids, adrenals, islets of Langerhans, and others, thus interfering with the anabolic processes. Growth and maintenance could not occur without some of the major internal metabolic catalysts.

There is no agreement on the answer to the question concerning the presence of a special somatotropic hormone independent of the other pituitary tropic hormones. The evidence favoring Evans' theory is that certain A.P. preparations injected at a proper age in susceptible animals induce gigantism in young animals (rats at any rate) and acromegaly in mature animals (some breeds of dogs at any rate), resembling the corresponding states in man suffering from certain types of pituitary tumor.

One of the outstanding effects in the production of gigantism is delay in epiphysial closure and stimulation of epiphysial cartilage³⁹²; hence the alternate name, chondrotropic hormone, for this pituitary growth factor(s).

The beneficial effects of pituitary administration to dwarfs is not proof of the presence of a special growth hormone, since crude pituitary contains tropic hormones for other growth-promoting glands which the dwarf may lack. Thus one pituitary dwarf began to grow after insulin therapy³⁹³, indicating that insulin (its production is also under A.P. control) has growth-promoting properties aside from its effect on carbohydrate metabolism. Similarly, adrenalectomy prevents bone growth³⁹⁴, and so adrenal deficiency

may be corrected by A.P. administration, as A.P. contains an adrenotropic hormone.

7.8: Notes on miscellaneous hormones

7.8.1: Hormones in evolution. The function of a given hormone may vary in different organisms, at different evolutionary levels. Thus in lower organisms, there are substances—such as estrin in insects, adrenaline in worms, oxytocic principle in fishes, progesterone in beans—which appear to be useless to them but which serve as hormones in more evolved organisms³⁹⁵. Moreover, a given hormone may act on different tissues in different species. Thus, lactogenic hormone stimulates the mammary gland to secrete milk, and the pigeon's crop gland to proliferate and to secrete "pigeon milk". The testicular hormone is required for the growth of antlers in the red deer, but not in the reindeer³⁹⁶. The ovarian hormone is necessary for sexual dimorphism of feathers in the fowl, but not in the sparrow, where it is controlled by the chromosomes of the epidermal cells³⁹⁷.

Keith³⁹⁸ in England and Stockard³⁹⁹ in the United States discussed the problem of hormones in evolution⁴⁰⁰. On the basis of his data Stockard concluded that breed characteristics of dogs are apparently due to endocrine peculiarities, and that these are transmitted in Mendelian manner.

Such characteristics as maleness, femaleness, broodiness⁴⁰¹, aggressiveness, and similar emotional patterns, or psychic states, so important in evolution, seem to reflect neuro-endocrine patterns. Indeed, the broodiness (maternal drive or maternal instinct in birds) may be measured quantitatively by the amount of prolactin in their pituitaries⁴⁰², and the potential genetic reproductive ability of domestic fowl may perhaps be measured by the quantitative response (increase in weight) of the gonads, thyroids, and combs on the administration of a given dose of anterior pituitary (gonadotropic and thyrotropic) extract⁴⁰³.

7.8.2: Endocrines in embryogenesis⁴⁰⁴. Embryonic growth and development are said to be stimulated by "hormones" named *evocalors*, particularly involved in the quantitative aspects of growth, and *individuators* or *organizers*, especially in developmental co-ordination, differentiation, and morphogenesis (Ch. 17).

In the egg stage, the individual exists in a potential form of extraordinary plasticity. The egg may divide to give rise to several individuals. Human identical (monozygotic) twins result from complete division of a single cell (Siamese twins from incomplete divi-

sion). The eggs of the Texas armadillo regularly divide into four parts, giving rise to four young. In some parasitic insects one egg often forms as many as 2000 separate embryos⁴⁰⁵. Spemann and others produced "secondary embryos" by "induction". But this plasticity rapidly declines with differentiation.

Spemann⁴⁰⁴ began his research to determine whether the causes of embryonic differentiation are chiefly intrinsic or extrinsic. He cut in two, in various planes, eggs and early embryos of newts. Prior to the gastrula stage, a whole embryo of half-size developed from each half of the egg, provided the cutting was in the median plane. Following the gastrula stage, when "labile determination" becomes "final", cutting of the gastrula results in abnormalities, and determination of the embryonic parts seemed to be fixed. The above discussion indicates that the destinies of the parts of the embryo are not fixed at the beginning, but become so only as development proceeds. These early potentialities rapidly disappear; each part acquires definite destinies which cannot be altered by experimental procedure. Spemann demonstrated the presence of growth organizers of various grades. He found that the *head organizer* would induce heads either in head or tail region (individuation), and that *tail organizers* would produce heads in the head region and tails in the tail region (evocation). The *competence*, the response of the receptor tissues to the organizer, to form head or tail is determined by the age of the tissues as well as by the organizer. Thus at first gill-forming competence is present over all the surface of the neurula, but later it is found only in the gill area.

The chemical nature of the evocator is indicated by the fact that it is not destroyed by boiling⁴⁰⁶. Coagulated dead pieces of dorsal lip induce secondary neural axes just as when living. Amphibian eggs coagulated by heat can produce new eyes and lenses when implanted⁴⁰⁷. Cell-free extracts from neurulae induce neural tubes when implanted in other embryos⁴⁰⁸.

The organizers are found at all ages. The adult mammalian liver is rich in them⁴⁰⁹. In other words, the decisive factor is not the presence of the "hormone", but the presence of the *competence* in the tissue to be affected by it. The concept of hormone and tissue-competence, or trigger-target, relation is true for all hormones and tissues at all ages. Thus the lactogenic hormone stimulates only the pigeon crop to grow and the mammary gland to secrete milk; estrogens stimulate only female genital tissue to grow and androgens stimulate male sex tissue. The organizers, like sex hormones, cortical sterides, and vitamin D, appear to contain the cholesterol ring (Fig. 7.1).

Cancerous growths and teratomata may be due to the presence of uncontrolled evocators or growth hormones, and also to the escape of tissues from the influence of the "individuation field" (Ch. 10).

The growth evocators may be suppressed by dietary factors. Thus a sow receiving a ration deficient in vitamin A may farrow pigs devoid of eye-balls⁴¹⁰ or limbs⁴¹¹. These defects may be expressions of faulty interrelations between vitamin, hormone, and target tissue (see, however, Sects. 7.3.2 and 20.2).

In closing, one is tempted to mention the spectacular reports on the growth-accelerat-

ing effects of thymus extract⁴¹³ (in the tenth generation the rats matured in about one-fifth the usual time) and growth-retarding effects of a pineal extract⁴¹³. These have not yet been confirmed⁴¹⁴.

The supposed growth-accelerating effects of the thymus extract were attributed to its glutathione, and similar results were said to have been obtained by injecting rats with glutathione⁴¹⁵. There is a wide belief that glutathione stimulates cell proliferation⁴¹⁶ (see also Ch. 6). The problem appears to be confused and seems to have been dropped for the moment.

7.8.3: Notes on green-plant hormones⁴¹⁷. As previously explained (Sect. 6.4.3), the members of the vitamin B complex of the animal nutritionist are identical with the members of the bios complex or the "growth factors" of the microbiologist. The self-sufficient green plants also need these factors, but green plants produce them internally, as animals produce hormones internally. Therefore, by definition (Sects. 6.1 and 7.1), these factors are vitamins (exogenous catalysts) to animals and hormones (endogenous catalysts) to the self-sufficient plants.

Plant hormones are produced not by endocrine glands (plants have none) but, perhaps, by the undifferentiated, rapidly growing embryonic tissues; formation of protoplasm and of hormones may be simultaneous in the same growth centers.

As is generally known, there is differentiation of functions between leaf, stem, and root; and looking back, it would seem natural to assume that some of the plant hormones might be produced in one part of the plant and not in another. This was indeed beautifully demonstrated as regards thiamine (vitamin B₁), pyridoxine (vitamin B₆), and nicotinic acid.

The demonstration, conducted by Robbins and associates at the University of Missouri, consisted in cultivating excised tomato-plant roots *in vitro* in a nutrient solution of sugar and salts, with and without vitamin supplements. These isolated roots did not grow on the basic sugar-salt solution, but did grow when supplemented with a crude yeast extract⁴¹⁸ and still better with whole yeast⁴¹⁹.

A search for the essential yeast constituents proved them to be thiamine⁴²⁰ and pyridoxine⁴²¹. A similar, independent investigation by Bonner⁴²² showed that excised pea roots need thiamine and nicotinic acid, and flax roots need only the thiamine supplement.

In addition to the vitamin type of plant hormone, there are others, the best known of which is auxin (auxin A and auxin B, or auxentriolic and auxenolonic acids).

The auxin was isolated (interestingly enough, from urine), structure determined, and

named by Kögl⁴²³. Auxin A has the composition $C_{15}H_{22}O_4$ and contains three hydroxyl groups forming a lactone. Auxin B has the composition $C_{15}H_{20}O_4$, an isomeric B-keto acid of auxin A. There are also many "heteroauxins", laboratory products which show auxin effects on plants, the best known and most effective of which is indole-3-acetic acid, also first isolated (from urine) by Kögl⁴²⁴.

Auxin is widely distributed, influencing, among other processes, the growth rates and thereby the growth form (Ch. 17) of plant embryos, seedlings, and stems. Many growth peculiarities and abnormalities are supposed to reflect corresponding patterns of auxin distribution. The auxin concentration in given positions may be influenced by temperature, light, gravity, x-rays, ultra-short radio waves, and certain gene peculiarities. Plant curvatures or tropisms (heliotropism, geotropism, etc.) are thus explained by the effect of light, gravity, etc. on the auxin distribution, with resulting differences in growth rates in the different parts. Photoperiodism of plants (Ch. 8) is similarly explained by Hamner. The upright growth of plants against gravity is explained by the pattern of auxin distribution. On the other hand, the "lazy" peculiarity (plant lies on the ground in accordance with gravitational pull) of some corn varieties is explained by lack of ability to shift auxin in response to gravity⁴²⁵. Plant dwarfism, as illustrated by the corn variety *nana*, is explained by excessive auxin destruction by the gene *nana*⁴²⁶, and so on.

The auxin effect on plant growth and development reminds one of the thyroxine effect on animal growth and development and of the influence of temperature and other factors on thyroxine concentration. The *dosage* effect of auxin on plants is similar to that of thyroxine on animals: there is only one optimal dosage; too little or too much leads to unfavorable results⁴²⁷. There also appears to be a similarity or analogy between the effects of auxin and thyroxine on "basal metabolism" or respiration rate⁴²⁸.

7.9: Summary. The introduction (Sect. 7.1) is an extensive summary of this chapter. Emphasis is placed on the interrelations between vitamins (exogenous catalysts) and hormones (endogenous catalysts). Special attention is given to interrelations between the various hormones in reproduction, lactation, growth, and in the metabolism of minerals, carbohydrates, and fat (ketosis); to the danger of disturbing hormonal balance and to the importance of considering incompatibilities between immediate and long-range efficiency of agriculturally productive processes related to hormone administration. The following quotation⁴²⁹ is an excellent summary of this balance concept.

"The most important concept in endocrinology which emerges from the feverish activity of the past decade is the principle of endocrine balance. Discovered and re-discovered by several investigators, the paradoxical truth has dawned finally that man or beast may suffer less from the loss of several glands than from losing a single one. For each of the precious juices the other secretions supply a partial antidote, so that health and personality may be preserved, delicately poised. Henceforth the practicing consultant and laboratory investigator, both, must think in terms of integrated hormonal effects".

Chapter 8

Metabolic Catalysts in the Efficiency Complex: Seasonal Rhythms

Once in each revolving year
Gentle Bird! We find thee here;
When nature wears her summer vest,
Thou com'st to weave thy simple nest.

Anacreon

Speaking teleologically, the breeding season is regulated by the times most suitable for the young to be produced and reared. *F. H. A. Marshall*

8.1: Introduction. The sun, some 93 million miles away, is the celestial limiting factor in life processes in furnishing not only energy (Ch. 2) but also catalysts which directly or indirectly condition many activities, one of the most dramatic of which is seasonal sex activity. This is not a new observation, as indicated by the above quotation (cited by Rowan) from Anacreon, 600 B.C. Systematic investigation of the involved clock-like timing is, however, recent. The purpose of this chapter is to present several new observations on the seasonal metabolic and growth rhythms of goats¹ and fowls² against the background of the literature.*

An evolutionary understandable but physiologically confusing arrangement is that breeding in different species occurs in different calendar months, depending on the length of the gestation period in relation to food supply and warmth; that is, mating occurs during such time as will be "most suitable for the young to be produced and reared".³ This means that each species has a different physiologic timing mechanism for responsiveness to the activating agents. Some species are stimulated to sex activity by increasing daylight, or/and increasing temperature (spring), others by decreasing daylight or/and decreasing temperature (late summer, autumn). Maize and soybeans bloom

* This chapter overlaps discussions in Ch. 7 on hormones and Ch. 11 on the influence of temperature on life processes (Figs. 11.19 and 11.20, influence of temperature on growth of chickens).

³ Marshall, F. H. A., *Phil. Trans.*, **228B**, 423 (1936); *Proc. Roy. Soc.*, **122B**, 413 (1937); *Biol. Rev.*, **17**, 68 (1942).

only when the days become shorter and reach a certain limiting *short* day; spinach and wheat bloom only when days become longer and reach a certain limiting *long* day. Deer, sheep, goats, and in general ruminating ungulates tend to come under natural conditions into sex activity when days become shorter; ferret, fox, field mouse, wildcat, hedgehog, and in general carnivores and insectivores, and practically all birds investigated (juncos, crows, canaries, starlings, turkeys, sparrows, doves, ducks, pheasants, quail, grouse) tend to come into sex activity only when days become longer. Horses, having a gestation period of about 11 months, breed in the spring (March-July) so as to foal the following spring.

Domestication tends to free animals from the seasonal influence and to shorten the estrus cycles. Thus dogs in the arctic regions have a single sharply-defined breeding period, similar to that of the wolf, jackal, and dingo; the domestic dog in temperate climate breeds twice a year and the time of breeding is not sharply defined. Likewise the wildcat breeds once a year, but the domestic cat breeds several times. The wild rabbit breeds in early spring, the domestic rabbit throughout the year. Wild cattle, like deer, breed in the autumn so as to calve in the spring; domestic cattle breed throughout the year. Domestic sheep, goats⁴, horses, and other species, however, still tend to cling to a more or less seasonal rhythm⁵.

Species evolved in the tropics and subtropics do not respond sexually to seasonal light stimuli. Thus the sex activity of guinea pig, guinea fowl⁶, subtropic deer⁷, and primates⁸ are apparently independent of season. The problem was recently debated⁹ as to whether primitive man, and contemporary man in the arctic, is seasonal, but with no conclusive decision. Fitt published an impressive essay on the seasonal rhythm in man, on the effect of spring.

"A spring rousing which is not merely a mechanical, physical process, but a highly emotional one as well, associated with the demands of the reproductive instinct, characterized by haste, restlessness, and a high measure of instability. This phase continues through the spring and summer until later, with autumn or thereabouts, the consolidating, quieter phase sets in. This

rhythm shows man to be still a creature of the sun, dependent upon its course through the seasons"¹⁰.

In brief, under natural conditions and in regions which have sharply defined climatic seasons, plants and animals pass a seasonal reproductive—and productive—rhythm, so adjusted as to be most favorable for the rearing of the young. The physiologic mechanisms whereby the sex activities are set into motion at different calendar months remain to be worked out and applied for increasing the efficiency (more frequent reproduction) and profit (as, for example, by "hatching pheasant chicks on Christmas day"¹¹) of productive processes.

8.2: Historical notes. In 1913 Turnois¹² observed that sex activity in some plants depends on days of definite duration. About 1920 Garner and Allard¹³ began publishing data on sex activity in plants in relation to daylight duration. They called this phenomenon *photoperiodism*. Since then a large literature has developed on the timing and on the mechanisms involved¹⁴.

Photoperiodicity in animals was discovered in connection with investigations of the mechanism of seasonal bird migration. In 1907 Sharpey-Schafer¹⁵ expressed the opinion that the ratio of daylight to darkness determines the seasonal migrations of birds "in consequence of the necessity to most birds of daylight for procuring food". It was known that the (spring) northward migration of birds is associated with enormous gonadal development. But this was attributed to temperature. Rowan¹⁶ first (1925) approached this problem experimentally, disproved the temperature theory for birds, and demonstrated that migration is dependent on light and "hormone elaborated by the developing gonads" (1938). Rowan substantiated the photoperiodic theory by subjecting juncos (finch) and crows to increasing daylight in December. "By the end of December, in spite of minimum reading of 52° below zero F, the birds that had been kept on increasing day length were singing and their gonads maturing". Electric lights (devoid of ultra-violet) were used in these experiments. The birds were brought into breeding condition or quiescence simply by lengthening or shortening the period of light exposure. However, the birds did not breed, because of inhibitory effects of captivity on the breeding habits of juncos. There is a difference between breeding condition and actual breeding¹⁷.

Bissonnette¹⁸ confirmed Rowan's results on starlings. Bissonnette¹⁹ and Baker and Ranson²⁰ extended the results to mammals.

While the seasonal reproductive periodicity in animals investigated by Rowan and by Bissonnette is photoperiodic (stimulus from visible radiations), there are many examples of thermoperiodic sex responses (stimulus from infrared radiations). Thus the breeding cycle in the white rat may be lengthened by lowering the room temperature²¹. Ovulation in bats will occur any time after the middle of February (in Columbia, Mo.) if they are brought into a warm room²²; but this varies with dietary and other habits of the particular bat²³.

Marshall reported that temperature is an important contributing factor to reproductive activities in deer:

"There is a common belief which is well attested that in deer general rut does not occur properly until there has been a sharp frost, that is to say, that a frost will awake both stags and hinds to their full sexual activity . . . if there is an exceptionally mild autumn, such as occurs only once or twice in a half-century, there is very little mating, and very few calves will be dropped in the following spring"²⁴.

The annual sex periodicity of the 13-lined ground squirrel is apparently not at all influenced by light.²⁵ The sex rhythm in the male²⁶ appears to be the same in "field" animals in dark hibernating burrows under natural conditions of life and in animals exposed to light rhythms in the laboratory. Moreover, ground squirrels, like deer, require a cool spell (+4°C) to enable them to breed²⁷. The pituitaries of these animals showed a seasonal rhythm in gonadotropic activity regardless of light effects.

It is generally known that plants respond to periodic thermal treatment. Such thermoperiodic induction is known by various names, such as "vernalization". When winter wheat is exposed during germination to a temperature a little above freezing, it will flower and fruit the same year, though sown in the spring. It is generally known that certain plants have to be nearly frozen every winter to make them grow the following spring.

8.3: Mechanisms of seasonal sex periodicity. It is agreed that sex activity has its basis in endocrine mechanisms controlled by the anterior pituitary. But sex activity is also dependent on many other factors such, for example,

as food. Light happened to be the *limiting* factor in the junco, crow, starling, ferret, and so on. Rowan²⁸ suggested that increased exercise associated with longer days might possibly be the "cause" of greater sex activity. However, Bissonnette²⁹ did not find this for the starling, and observed that ferrets responded to light even if they could not move, even when they were approaching death from tuberculosis.

It has been established that the pituitary in photoperiodic animals responds with profound histological changes to changes in the day/night ratio³⁰, and that hypophysectomized ferrets are unaffected by light variations.³¹ However, the later observation is, perhaps, without significance because hypophysectomy abolishes sex activity and subjecting to light does not regenerate the pituitary.

Assuming that light exerts its seasonal effect by way of the pituitary, several investigated the path of transmission of the stimulus. Reports indicate that cataract of both eyes³² (but not of one³³) abolishes estrus for some time, as does cutting the optic nerve (in ferrets)³⁴, and there develops instead an inherent sex cycle by "alternate rise and fall in secretion or liberation of gonadotropic hormones"³⁵, independently of light.

In brief, blind photoperiodic animals tend to have their photoperiodic cycle replaced by an "inherent" sex cycle independent of the light periodicity. This inherent cycle is apparently not as reliable as the photoperiodic cycle³⁶. Covering the eyes also tends to disturb the photoperiodic sex effect³⁷. However, this is not always the case³⁸.

Summarizing, the eye is normally the light receptor in photoperiodic animals. When the eye is removed, the optic nerve may, perhaps, serve as receptor when light is directed into the eye socket (Benoit); the naked skin may, perhaps, be a receptor (Ivanova). The light probably initiates nervous impulses which travel to the hypophysis by way of the hypothalamus³⁹. Some species are freed from the photoperiodic influence by domestication, that is,

by supplying food and warmth throughout the year, indicating that photoperiodicity is dependent on many other factors, food and warmth being the most obvious.

8.4: Seasonal food supply rhythms in relation to seasonal sex activity.

There is a seasonal rhythm not only in the amount but also in the nature of the food supply, herbage, and other feeds and foods. Milk is much richer in vitamin D (Fig. 8.1A)⁴⁰, vitamin A (Fig. 8.1B)⁴¹, and in other vitamins and fatty acids⁴² in summer than in winter. (Compare the seasonal rhythm in vitamin D concentration, Fig. 8.1A, with that of the ultraviolet radiation,

Fig. 8.1a—Seasonal rhythm of vitamin D concentration in milk.

Fig. 8.5C.) There are similar seasonal rhythms in vitamin D, phosphorus, and calcium concentration in blood, which are opposite in trend to the seasonal incidence in rickets⁴³. A reproductive aspect of vitamin D or sunlight is illus-

trated by the result of Lucas, Hume and Smith⁴⁴, whose marmosets refused to take cod liver oil and failed to breed. Irradiation with ultraviolet light corrected the breeding difficulty.

Friedman⁴⁵ reported the presence of gonad-stimulating substances in immature oat plants, sudan grass, corn plants (but not in kidney beans, brown corn, sorghum, or soybeans). Injecting 60 mg of one plant preparation produced ovulation in the rabbit and ovarian stimulation in the rat. Copper salts, in which immature plants are rich, are also gonadotropic⁴⁵, or at least augment

Fig. 8.1b—Seasonal rhythm of vitamin A potency in milk.

the activity of the gonadotropic hormones; 3.5 mg copper (as sulfate or acetate) produced ovulation in the rabbit. Young grasses are rich in many other factors such as the "grass-juice" factor, vitamin E, vitamin A, vitamin B complex (Ch. 6), and limiting amino acids⁴⁶.

The seasonal thyroid rhythm (Figs. 8.2A⁴⁷ and 8.2B⁴⁸) may be related to the seasonal rhythms in availability of iodine and related dietary constituents. As might be expected from the seasonal food-supply rhythms, the iodine percentage in the thyroid increases in spring, reaching a maximum in summer (July) and declining thereafter to a minimum in late winter. The size of the gland tends to follow an opposite course. There is no rhythm in

Fig. 8.2a—Seasonal rhythm of iodine content in thyroid.

iodine content of blood⁴⁹. The thyroid is an important factor in the reproductive and productive processes (Ch. 7).

8.5: Seasonal periodicity in relation to efficiency with special reference to egg and milk production. Reproductive efficiency, of course, increases with

increasing reproductive frequency (see Figs. 8.3 and 8.4), and the profit increases on timing the breeding to suit the convenience of the farmer. The following examples indicate the potentialities of this type of research.

Ferrets were brought into estrus during the winter season by the use of light⁵⁰. Similar results were obtained on field mice⁵¹. Winter breeding was induced⁵² in the raccoon, pheasant, quail, and ferret. Cole⁵³ obtained eggs from mourning doves months earlier than the usual laying season by appropriate light conditions. Grouse⁵⁴ were brought into laying about 1 month earlier by continuous lighting (not changing day-to-night ratios) beginning February 10.

Fig. 8.2b—Seasonal rhythm in thyroid weight.

Poikilotherms are also photoperiodic; Hoover⁵⁵ induced winter breeding in brook trout 3 to 3½ months earlier than the normal spawning season. Scott and Payne⁵⁶ found that May-hatched turkeys exposed to electric lights from

Fig. 8.3—Parallelism between the seasonal rhythms of productivity and gross efficiency of egg production.

Fig. 8.4—The influence of latitude on the seasonal rhythms of egg production.

4:30 a.m. until natural daylight, during December, were brought into egg production in January, whereas control birds produced no eggs until early March. Only white light or longer wave-lengths stimulated early production; blue light failed to exert this effect.

There are many reports⁵⁷ on the use of light in poultry houses for increasing egg production in winter. But such winter lighting is not photoperiodic in the sense of gradual increase or decrease of light. The lights are turned on at 4 or 5 a.m., merely giving the birds a "longer working day" during the

Fig. 8.5a—Monthly temperature rhythms corresponding to the latitudes given in Fig. 8.4.

period when egg prices are high. The following statistical data on the seasonal rhythm in egg production are cogent in this connection⁵⁸.

Fig. 8.4 shows that near the equator, egg production in the domestic fowl is relatively uniform throughout the year; in the upper latitudes of northern hemisphere, maximum production is in April and minimum is October-No-

vember; in the southern hemisphere, maximum production is in October-November and minimum in April.

Corresponding to the dependence of egg production on latitude, Marshall's⁵⁹ observation on the sex behavior of sheep and deer may be cited. After being transported from the northern to the southern hemisphere, sheep and deer bred not in the customary calendar month but in the month corresponding to autumn in the new latitude.

Fig. 8.5b—Monthly sunlight rhythm, average and possible in Cleveland, Ohio, data by Luckiesh et al. Courtesy J. P. Ditchman, General Electric Co.

The corresponding curves for average sunshine and temperature are shown in Fig. 8.5, which indicates the nature of the parallelism between the course of seasonal sex activity in the fowl and the course of seasonal changes in day-light duration.

Dr. V. S. Asmundson⁶⁰, University of California, has kindly furnished data on the seasonal rhythm of egg production in the turkey, which we plotted in Fig. 8.6. The broken curves in Fig. 8.6 indicate the seasonal sunshine rhythms

Fig. 8.7—Seasonal rhythm of egg production in quail. Plotted from unpublished data by E. M. Funk of this Station.

University of Missouri kindly supplied data on egg production in quail, plotted in Fig. 8.7.

We are not familiar with experimental investigations on photoperiodic

responses of domestic mammals, although goats⁶¹ and sheep offer suitable material for such work.

Just as egg production in birds is maximal in spring, so is milk production in mammals (Fig. 8.9). It so happens that spring is not only the season of birth under primitive or natural conditions, but is also the season in which pasture is in its prime as nutrient for milk production, and the temperature is most favorable. The high spring milk production is probably the resultant of

Fig. 8.8—Seasonal rhythms of egg production in chickens with increasing age, plotted from Brody, Kempster and Funk, Mo. Res. Bull. 278, 1938. The numerals in circles represent the number of original survivors in successive years. The circles represent all the birds under observation at successive years; the X's represent the same birds which produced for full 9 years.

all these factors, but mostly of feed and temperature. As summer advances, the temperature rises (cattle are exceedingly sensitive to high temperatures Ch. 11, Fig. 11.17), feed quality declines, insects become more pestiferous and perhaps the primitive or "natural" lactation urge tends to terminate. All these factors probably contribute to the late summer decline in milk production, but temperature and decline in the nutritional quality of the feed, are most important (Fig. 810b).

⁶¹For the photoperiodicity of goats see Bissonnette, *Physiol. Zool.*, 14, 379 (1941).

As far back as 1909 Eckles⁶², from the Missouri Station, made it generally known that the milk solids (especially butter fat, which determines the commercial value per unit milk) vary inversely with the milk-production level; consequently, the solids percentage in milk (except for vitamins and electrolytes) also shows a seasonal rhythm with a minimum in spring, when milk production is maximum, and maximum in winter when milk production is minimum (Fig. 8.9A to C).

Fig. 8.9a—Seasonal rhythms in milk production. The charts are self-explanatory. The data compiled from various sources were tabulated in Univ. Missouri Agr. Exp. Sta. Res. Buls. 96 and 105. Several references including Sherman's data for sugar are given in the text. Note that milk yield tends to be maximal in May. When milk yield rises, left axis in 8.9a, fat per cent and other solids tend to decline, right axis in 8.9a. The maximal yearly yield is obtained when calving in autumn (Fig. 8.10b).

The month of calving exerts considerable influence on the persistency of the milk flow. It is usually more persistent in dairy cattle calving in the autumn, because when the flow would normally decline, about six months after calving, it gets a lift from the spring pasture and from the other favorable conditions associated with spring.

The month of calving tends to exert a similar influence on the maximum annual milk production as on the maximum persistency: calving in late autumn tends to yield the highest annual production, as shown in Fig. 8.10b.

⁶² Eckles, C. H., "Jahreszeitliche Schwankungen des Prozentischen Fettgehaltes in Kuhmilch," *Milchwirtschaftliches Zentralbl.*, 5, 448 (1909).

The literature is not, however, fully consistent⁶³ on this point; it depends, no doubt, on the locality in which the data are obtained.

Fig. 8.9b—See legend 8.9a.

8.6: Seasonal growth and metabolic rhythms. The seasonal rhythm in food supply, sunshine, and warmth should influence the rates of growth and metabolism, which they do.

We shall not attempt to review the literature on seasonal growth rhythms (Palmer⁶⁴ and McKay⁶⁴ discuss the literature) but list⁶⁴ illustrative references and quote one chart on seasonal growth of children by Palmer, Fig. 8.11.

Fig. 8.9c—See legend 8.9a.

There is, as usual, considerable disagreement in detail; but the facts appear to be that weight growth in children tends to be most rapid (about 1 pound

Fig. 8.10b—See legend 8.9a.

per month) during autumn (September to November in northern latitudes, and April to June in southern latitudes); and least rapid (about $\frac{1}{4}$ pound per month) in the spring. (See Fig. 11.19 for an apparently seasonal growth rhythm in chickens, which is, however, a temperature effect.) There is also literature on annual energy-metabolism rhythms⁶⁵.

There are difficulties in interpreting seasonal metabolic data because factors other than season as such (*i.e.*, length of day, angle of the sun's rays, temperature, and related cosmic⁶⁶ influences) confuse the picture. Gestation

Fig. 8.11—Seasonal rhythm of growth of children, from C. E. Palmer, *U. S. Public Health Reports*, 48, 211, 1933. Reprint 1561.

and lactation, for example, as well as differences in feed supply and temperature are confusing factors in interpreting our seasonal goat data.

With these difficulties in mind, let us discuss briefly the interrelations between the metabolic (energy metabolism) and breeding rhythms. As regards energy-metabolism rhythms in humans, Gustafson and Benedict⁶⁷ found no significant rhythm in body temperature, "but the average values for the oxygen consumption strongly suggest that the metabolism tends to be at a low level in the winter and to rise to a higher level during the spring and summer."

Fig. 8.12a—Seasonal rhythm in resting metabolism (R.M.) and of conception in goats (lower left), metabolism and birth in goats (lower right), metabolism and weight gains in goats (upper left) and resting metabolism (R.M.) in goats and basal metabolism in man (upper right).

We have investigated⁶⁸ the seasonal energy-metabolism and growth rhythms in goats and compared them with the seasonal breeding⁶⁹ rhythms. The results are shown in Fig. 8.12a. We also present in this chart the basal-energy

⁶⁷ Gustafson, F. L., and Benedict, F. G., "The seasonal variation in basal metabolism," *Am. J. Physiol.*, **86**, 43 (1928).

⁶⁸ Brody, Sandburg, and Asdell,¹ 1938.

⁶⁹ Asdell, S. A., *J. Agr. Sci.*, **16**, 632 (1926). Turner, C. W., *J. Dairy Sci.*, **19**, 619 (1936).

metabolism data of humans kindly placed at our disposal by Professor Fred R. Griffith,⁷⁰ University of Buffalo. All the data were plotted in terms of percentages as follows.

The lowest average monthly metabolism was taken as base line. This base value was deducted from each monthly metabolism (average) and the differences were plotted against the corresponding months as percentages of the average monthly metabolism

Fig. 8.12b—Seasonal growth and metabolism rhythm of a castrated sheep.

increment. Similarly, the monthly weight gains were plotted as percentages of the yearly average of the monthly weight gains and the monthly breeding frequencies. In this way the metabolism, growth, and sex activity rhythms become comparable.

⁷⁰ Cf. *inter alia*, Griffith, F. R., Jr., and his associates: "I. Metabolism and oral temperature," *Am. J. Physiol.*, **87**, 602 (1929); "II. Pulse rate and blood pressure," *Id.*, **88**, 295 (1929); "III. Alveolar air and blood gas capacity," *Id.*, **89**, 449 (1929); "IV. Vital capacity, respiratory rate and volume, and composition of expired air," *Id.*, **89**, 555 (1929); "V. Urine Chemistry," *J. Nut.*, **5**, 131 (1934); "VI. Blood Chemistry," *Id.*, **6**, 169 (1934).

Fig. 8.12a shows that the metabolic peak in goats (as in sheep) occurs in early spring. The weight gains in growing goats are also maximum in early spring. The breeding peak, on the other hand, occurs in the autumn. The tentative conclusion, therefore, is that there is an inverse relationship between high breeding level and high energy-metabolism level.

We plotted Griffith's human data on the upper right corner of Fig. 8.12a as we did our goat data, in terms of percentages of average annual metabolism increment above the base level. The time curve of metabolism of humans is similar to that of the goat in spite of the fact that humans do not have an annual sex rhythm in temperate zones. Fig. 8.12b represents the seasonal rhythms in a castrated sheep, with a spring maximum.

Fig. 8.13a—Seasonal metabolic and reproductive rhythms in the domestic fowl, also sun rhythm in Columbia, Mo.

We have also investigated the seasonal rhythm of basal heat production in domestic fowl⁷¹ (Fig. 8.13a) which indicates a parallelism between basal metabolism and egg production. This does not mean that a high reproduction rate as such is associated with a high metabolism rate. The high basal metabolism during high egg production in the fowl may reflect the massive energy transformations associated with egg production rather than with primary reproductive activity. As shown in Fig. 8.12a, the peak metabolism in goats (R. M. = "resting" metabolism, 12 hours after feeding, which is not post-absorptive in this species) coincides not with maximum breeding activity, as in the fowl, but with minimum breeding activity. The seasonal rhythm in

⁷¹ Winchester, C. F., Univ. Missouri Agr. Exp. Sta. Res. Bull. 315, 1940.

heat production is thus a problem in multiple causation rather than of simple cause and effect.

Many other rhythms might be cited, such as the seasonal rhythm of receptivity of the capon's comb to androgens reported by David⁷² and by Laqueur⁷³. Duszynska⁷⁴ reported that the response of castrated mice to estrone is three times as great in May as in November. It is evident that season influences the sensitivity of the receptive as well as of the "causative" organs.

One could discuss other seasonal rhythms, such as those of blood volume (Ch. 11, Bazett), hemoglobin concentration, calcium, phosphorus, blood fat, and blood coagulation (most rapid in the summer). In connection with Fitt's theory of spring instability mentioned in the beginning of this chapter, and Bazett's "torrents of spring" (Ch. 11), it is interesting to note that the suicide peak is maximum in spring (Fig. 8.14).

One could also discuss the seasonal hibernation-rhythm phenomena based on the marmot⁷⁵ (ground-hog) so famous for its weather-prognosticating abilities (on February 2 it is supposed to wake up, and if it sees its shadow, it promptly retires to its hibernation because of forthcoming cold weather within six weeks). During the summer its body temperature, pulse rate, and respiration rate are of the same order as of non-hibernating mammals of the same size. In autumn, however, when the environmental

Biol.*, 6, 439 (1931). Rasmussen, A. T., *Am. Naturalist*, 1, 609 (1916); *Endocrinology*, 5, 33 (1921). (The hypophysis in the woodchuck with special reference to hibernation"). Herter, K., "Körpertemperatur und Aktivität beim Igel," *Z. vergl. Physiol.*, 20, 511 (1934).

temperature drops to 50–60°F (10–15°C), and, incidentally, the food supply decreases, it goes into hibernation; its body temperature falls from the normal 37° to 30°C, to 15°C, and finally to 6°C, or even 3°C (37° to 43°F). The pulse drops from the normal of 200 per minute to perhaps 4 to 5 per minute. Unlike cold-blooded animals, however, when the environmental temperature drops below 42°F (6°C), it wakes up, thus preventing it from freezing to death. These animals are thermo- rather than photoperiodic.

8.7: Summary. Many species are photoperiodic. Domestication under special conditions of food supply tends to disturb this photoperiodism. This modification of the breeding pattern may be due to an interrelation between the feed supply and sunlight, perhaps similar to the interrelation between sunlight and dietary vitamin D, calcium and phosphorus salts.

Fig. 8.14—Seasonal suicide rhythm in the United States (plotted from U. S. Bureau of Census, Vital Statistics Special Reports, Vol. 3, No. 11, p. 67, April, 1937, and Vol. 5, No. 20, p. 55, March 1938. Not indicated by sex).

On the other hand, many domestic species are decidedly seasonal in their breeding pattern, perhaps dependent on the seasonal light pattern.

The seasonal metabolic rhythms parallel the reproductive rhythm in the fowl (spring peak, Fig. 8.13a), but not in the goat (conception peak in autumn, metabolic peak in spring, Fig. 8.12a). The metabolic rhythm parallels the growth rhythm in the goat (spring peak, Fig. 8.12a), but not in man (metabolic peak in spring, Fig. 8.12a, growth peak in autumn, Fig. 8.11).

The breeding season is timed so that the young will be born during the most favorable time; hence the breeding time is related to the length of the gestation period, to the environmental temperature, and to food supply, all of which are in turn related to sunlight. Hence the tremendous species differences in sensitivity to day length: some species are stimulated to sex activity by shortening days, others by lengthening days. Still others are apparently unaffected by day length.

The anterior pituitary is thought to be involved in photoperiodic gonadal activity. It is assumed that light falling on the eye stimulates (by nervous channels) the pituitary to produce gonadotropic hormone. Thyroid activity, which is sensitive to changes in temperature and light irradiation, may be an influencing factor.

While sudden changes in day length may induce sex activity, they may not result in increased fertility because of premature and abnormal maturation of the sex cells, and because of high mortality. For normal breeding out of season, graduated changes in day length simulating the natural seasonal changes in day length may be required. There is an obvious need to investigate these phenomena as they relate to farm animals and thus to learn to control their timing.

Chapter 9

Metabolic Catalysts in the Efficiency Complex: Diurnal Rhythms

Science started with the organization of ordinary experience. A. N.
Whitehead

9.1: Introduction. We became interested in the problem of diurnal rhythm when we obtained some unexpected results in a study¹ of the heat increment of feeding (*SDA*, Ch. 4) of the rat. The anomalous result could be explained only by assuming the presence of a diurnal metabolic rhythm in which the difference between crest and trough exceeded the *SDA* effect of the feed (Fig. 9.1). This led to the performance of a series of experiments, and the discovery of a profound (25–30 per cent difference) diurnal metabolic rhythm in the rat which is not extinguished by a month of continuous light *alone*, by a month of continuous feeding *alone* ($\frac{1}{3}$ of the day's maintenance ration at 3-hour intervals), nor by a combination of continuous light and fast. It is extinguished, however, by a week of continuous light *and* continuous feeding. The object of this chapter is to summarize some of these results and integrate them with the literature on diurnal rhythms in general as a logical sequence to the preceding chapter on seasonal rhythms in general, with special reference to the efficiency complex.

There is an evident analogy between diurnal and seasonal rhythms, both being ultimately activated by the sun rhythm; and metabolic effects—however different in nature—are exerted not only on photosynthetic plants but also on animals endowed with visual or related extroceptive apparatus. The timing of the rhythmic activity in animals, whether they are diurnal or nocturnal, depends on the nature of their visual apparatus, whether they see best in bright light (day) or in dim light (night). The diurnal light rhythm, through the intermediacy of the amplifying visual apparatus, exerts a profound effect on all life processes. Sleep is a conspicuous illustration; so are there rhythms in body temperature and nervous irritability which are inter-related with muscular activity, with energy metabolism, with food intake, and so on. It seems instructive to review the literature in some detail so as to get a view of the situation as a whole.

¹ Herring, V., and Brody, S., "Diurnal metabolic and activity rhythms," Univ. Missouri Agr. Exp. Sta. Res. Bull., 274, 1938.

9.2: The literature. When travelling, the *body temperature* rhythm follows the light rhythm². In man, the average minimum daily temperature, 36.5° C, is in the early morning (2 to 5 a.m.) and the maximum, 37.5° C, in the afternoon (2 to 5 p.m.). In the pigeon³ the midnight temperature, 41.5° C, is below the noon temperature, 42.2° C.

The most dramatic feature of the diurnal rhythm is *sleep*. Kleitman⁴ gave a good description of its natural history in man (1929).

"Darkness makes for poor vision and discourages movements. This leads to inactivity and relaxation, and sleep follows. Repeating the performance a great many

Fig. 9.1: Apparent difference in heat increment of feeding in rats following morning and afternoon feeding.

times results in the establishment of a conditioned reflex of a temporal character, relaxation at a certain time. This is the theoretical history of diurnal sleep.

"Practically we are born into a social organization where diurnal sleep is the uni-

² Gibson, R. B., "Body temperature periodicity," *J. Med. Sci.*, **129**, 1048 (1905). Osborne, W. A., *J. Physiol.*, **36**, p. XXIX-XLI (1908).

³ Burckard E., Dontcheff, L., et Kayser, C., "Le rythme nycthérméral chez le pigeon," *Ann. physiol. physicochim. biol.*, **9**, 303 (1933). For other body temperature rhythms see Simpson, S., and Galbraith, J. J., "Body temperature variations of nocturnal and other birds, and mammals," *J. Physiol.*, **33**, 225 (1905); Wetmore, A., "A study of the body temperature of birds," *Smithsonian Misc. Coll.*, **72**, 1 (1921).

⁴ Kleitman, N., "Sleep," *Physiol. Rev.*, **9**, 624 (1929). "Sleep and wakefulness," Univ. Chicago Press, 1939.

versally accepted mode of sleeping. The first habit that a mother tries to develop in a baby is that of an unbroken night's sleep. As he gets older other functions develop a periodicity that coincides with the enforced sleep periodicity. For instance, a temperature curve develops with a minimum at night, and produces a disinclination to night activity. Even the modest tear apparatus stops its function at bedtime procuring dry eyes, favoring their closure."

Nervous irritability follows a similar rhythm. The reaction of normal man to light and sounds is lowest in the morning, when body temperature is lowest, and increases with increasing body temperature in the afternoon, then returns to the morning minimum. When the body temperature is at a minimum, irritability is likewise at a minimum, and it is then most difficult to keep awake. Skills of coordination are at a minimum during these early hours⁵.

The influence of nervous irritability on metabolism and body temperature may be inferred from the facts that about half of the peripheral nerves supply the skeletal muscles and about half of the body mass is muscle. The increase of the contractions of skeletal muscle is proportional to the increase in nervous irritability⁶.

The literature on the *development of activity rhythms* is somewhat conflicting. Thus Richter⁷ reported that the rhythms gradually develop (first appear in rats about 12 days after birth), presumably because of social conditioning. Barott⁸, on the other hand, reported that the metabolic rhythms "decrease rapidly with age" in young chicks. "At the average age of 1 week . . . an average maximum difference of about 24 per cent was observed between the oxygen consumption at 8 a.m. and 8 p.m. values." (The peak occurred at 8 a.m. and the trough at 8 p.m.)

Richter⁷ reported that the diurnal rhythmic activity of the fasting rat persisted even in the absence of light cycles. On fasting, during the early period of fast, the total activity was greater than during five previous feeding days. We found the same to be true.

The *feeding rhythms* naturally follow the activity rhythms, being usually confined to times when vision functions best, which is night for rats and other nocturnal animals and day for fowl and other diurnal animals. There are corresponding nutrition-function rhythms. Thus glycogen storage in rabbits, rats, and mice is maximal and bile formation is minimal during the night⁹. In nocturnal animals, the assimilatory phase when the glycogen

is deposited occurs during the night when the animals naturally feed¹⁰. The glycogen deposition at this time tends to be counteracted, however, by physical activity; this occasionally results in a bimodal curve of glycogen storage.

In diurnal animals the blood-sugar and adrenaline peaks occur during the day (and the calcium peak at night), opposite to the liver glycogen peak¹¹. Incidentally, in diabetics the blood-sugar level falls during the evening, often below the fasting level¹². Lactating cattle tend to exhibit blood-sugar rhythms¹³. The trend is likely to be confused because of the sensitiveness of the blood-sugar level to psychic disturbances involved in securing the blood. (In lactating cows the blood-sugar level reached a high of 70 mg sugar per 100 cc blood at noon and a low of 58 mg at 9:30 a.m. There was no such trend in non-lactating cows or sheep.)

Diurnal rhythmicity was also reported for blood volume¹⁴, non-protein nitrogen¹⁵, serum calcium¹⁶, red corpuscles and hemoglobin¹⁷, water and minerals¹⁸.

There is an apparent diurnal rhythm in the composition of milk¹⁹ (Fig. 9.5). The diurnal difference in fat percentage is attributed to differences in time-interval between day and night milkings. Morning milk is richer in bacteria than evening milk, and evening milk is richer in chlorine and catalase than morning milk²⁰.

Domestic fowl lay eggs only during the day (7 a.m. to 5 p.m.)²¹.

The "alkaline tide"²² (urinary-acidity rhythm) is obviously associated with the diurnal feeding rhythm. The sensitiveness of urinary reaction to diet is indicated by the fact that ingestion of 5 g sodium biocarbonate results in an immediate rise in alkalinity of the urine. The urinary-volume rhythm tends to parallel the body-temperature rhythm²³. The blood pH in humans rises from morning to late at night²⁴.

The stomach-activity rhythms are presumably associated with feeding habits. There is an extensive literature on this problem²⁵.

Many miscellaneous diurnal rhythms have been observed, such as the mitotic rhythm in human tissue²⁶, spermatogenic rhythm in the sparrow²⁷, enamel deposit rhythm in the rat²⁸, retinal rhythm in catfish²⁹, brain-potential rhythms³⁰, cell-division rhythm in the thyroid³¹, and so on.

According to Szymanski³², in addition to diurnal rhythmicity, some species are *polyphasic*, exhibiting several periods of activity and rest during the day; others are *monophasic*, exhibiting one prolonged period of activity followed by one of rest during each day. Rabbits are polyphasic, having 16 to 21 periods of activity alternating with rest; albino rats have 10 periods of activity concentrated, as in other nocturnal animals, at night; canaries are monophasic, active during day and quiet during night; young dogs exhibit 8-13 periods of activity at night; cats exhibit $\frac{2}{3}$ of their activity during the day, and $\frac{1}{3}$ during the earlier part of night; human infants are polyphasic, human adults monophasic, with the aged resembling infants in being polyphasic. There are obvious difficulties in differentiating between such inherent phasic rhythms and merely spurious movements.

We are mostly interested in the energy-metabolism rhythms, which reflect all the others.

Lusk^{32a} quotes the following table from Johansson on the diurnal rhythm of CO₂ production in man:

	Night CO ₂	Day CO ₂	Author
Complete muscular rest	100	105	Johansson
Ordinary rest in bed	100	110	"
Ordinary life (no hard work)	100	142	Tigerstedt
" " " " "	100	128	Pettenkofer and Voit
" " " " "	100	147	Tigerstedt

Benedict and Riddle³³ reported that muscular activity of pigeons in dark chambers is less during night than during day. After excluding the periods showing muscular activity, day metabolism was about 15 per cent above night metabolism.

³³ Benedict, F. G., and Riddle, O., "The measurement of the heat production in pigeons," *J. Nut.*, **1**, 475 (1929).

The pigeon was reported to have a 15 per cent diurnal basal metabolism and a 1° C rectal-temperature rhythm³⁴. The fowl was reported to have a 30 per cent basal metabolism and a 1° C rectal-temperature rhythm³⁵. The following (slightly rounded) data on rectal temperatures in fowl from Heywang³⁶ are illustrative of the course of the rhythm.

Time	8 a.m.	10 a.m.	12 noon	2 p.m.	4 p.m.	6 p.m.	8 p.m.	10 p.m.	12 night	2 a.m.	4 a.m.	6 a.m.	8 a.m.
Rectal temp. (°F)	106.8	106.5	106.4	106.4	106.8	106.8	105.9	105.5	105.4	105.6	105.9	106.3	106.5
Environmental temp. (°F)	53	68	74	79	76	64	56	50	48	46	44	42	54

Note that the environmental temperature happened to be changing at the same time, and Heywang suggested that there might have been a causal or dependent relation between rectal and environmental temperature. Of course, all aspects are interrelated, but it appears from other data that, in the main, the rectal-temperature *rhythm* would not have decreased appreciably if the environmental temperature had been kept constant at the mean value of about 60° F.

Kayser³⁴ demonstrated that the diurnal metabolic rhythm in the pigeon is due to the diurnal variation in tonicity of posture, especially of the pectoral muscles, which in turn is caused reflexly by the excitation produced by the diurnal light rhythm upon the nerves controlling muscle-tone.

Several reports are available on the inversion of body temperature obtained in animals by changing the light rhythm. This was accomplished on monkeys³⁷ and birds³⁸ in about 15 days. The results in inversion of body temperature and metabolism on man, however, are conflicting³⁹, because it is difficult to isolate him psychically and intellectually from the social rhythm of the environment even though he is isolated from the light rhythm.

The persistence of the diurnal rhythm in spite of prolonged rest and fast stimulated speculations on cosmic influences other than the sun, including cosmic rays and ionized air⁴⁰. Deighton⁴¹ observed a diurnal rhythm in

metabolism of swine screened from changes in electrical conductivity. As previously noted, the thyroid, the prime metabolic regulator, has a diurnal growth (cell-division) rhythm.

9.3: Diurnal metabolic rhythm in the rat, its control and effect on the apparent SDA. The heat production per hour is the sum of: (1) the basal energy metabolism; (2) the energy expense of muscular activity and muscle tonus; and (3) the *SDA* (Ch. 4). As the rat is nocturnal, his muscular activity, nervous irritability, muscle tonus, feeding, and body temperature tend to be high during the night when his vision is best and low during the day when his vision is poorest. We may then expect high metabolic rates

Fig. 9.2. The continuous line represents the average of the data for the 6 rats in Fig. 9.1. The area between the broken curves includes $\frac{2}{3}$ of the data.

during the night and low metabolic rates during the day, just as Kayser found the opposite conditions in the pigeon. Our problems were: (1) to evaluate under our laboratory conditions the magnitude of the "normal" diurnal rhythm; (2) to investigate the conditions which may abolish the rhythm and thus obtain an insight into the mechanisms involved.

The magnitude of the diurnal metabolic rhythm under "normal" conditions is shown in Figs. 9.1 to 9.3; there is 25 to 30 per cent difference between the peak and crest in the curve.

The investigation on abolishing the rhythm brought to light several facts: (1) The muscular activity and metabolic rhythms are parallel. (2) Continuous lighting alone for a month did not abolish the diurnal rhythm. (3) Continuous feeding alone (feeding $\frac{1}{3}$ of the day's maintenance ration every 3

Fig. 9.3. Diurnal metabolic rhythms of white rats under continuous light of constant intensity when fasting (upper curve), and when consuming $\frac{1}{4}$ of the maintenance ration at 3-hour intervals throughout day and night for over a week (lower curves). The rhythm is maintained in the fasting rat, but is extinguished in the continuously feeding rats, so that only residual "autogenous" rhythms remain.

hours) for a month did not abolish the rhythm. (4) A week of fast under continuous lighting did not abolish the rhythm. (5) But a combination of continuous lighting and continuous feeding ($\frac{1}{3}$ of the daily ration every 3 hours) extinguished both the activity and the metabolic rhythms.

The metabolic result of fast under continuous lighting is shown in the top curve of Fig. 9.3. The first midnight peak is above the other peaks because it includes the heat increment of feeding (*SDA*) of the prefasting meal (6.4 g feed eaten at 3 p.m.); it includes, in other words, (1) the *normal* 25 per cent

Fig. 9.4. Diurnal activity in the rat measured by the revolution in an exercise drum.

diurnal metabolic difference and (2) a 25 per cent feed intake effect. This is shown by the following data:

24-hour period of fast	Metabolism				Difference (%)
	Cal/day	Maximum time	Cal/day	Minimum time	
1	37.4	midnight	24.4	3 p.m.	53.3
2	30.7	9 p.m.	23.2	3 p.m.	52.3
3	30.2	midnight	24.1	3 p.m.	25.3
4	30.2	3 a.m.	24.0	noon	25.8

In one trial, one group of rats was fed a 10-gram meal at 4 a.m. which was followed not by a rise but a decline in metabolism until noon (8 hours); another group of rats was fed a 10-gram meal at 4 p.m. which was followed by a steady increase in metabolism, reaching a 40 per cent peak increment in 5 to 7 hours; it then declined to a minimum in 16 hours. It is thus evident that there is an algebraic summation of the effects of feed-intake and diurnal rhythm. If the animal feeds during the ascending slope (after 3 p.m.) of the diurnal rhythm, there is a reinforcement of effect with a resulting abnormally high metabolic peak; if it feeds during the descending slope of the rhythm (after 3 to 5 a.m.), the *SDA* is apparently below normal.

The metabolic results on continuous feeding (feeding 1.5 g food every 3 hours day and night) are shown in the middle and bottom curves in Fig. 9.3. Many metabolic, muscular-activity, and respiratory-quotient curves of individual animals and of their averages confirm⁴² those in Figs. 9.3 and 9.4.

"Welsh⁴³ argued that most diurnal rhythms are 'inherent', since prolonged periods of either continuous darkness or light do not always abolish the rhythms. The diurnal activity rhythm in the rat⁴⁴, among others, was cited as an illustration of 'inherent' rhythm. However, we have clearly demonstrated that the diurnal activity and metabolism rhythm in the rat can be quickly abolished under continuous light, provided that this is combined with continuous feeding; and that the rhythm in the young is developed by "social conditioning". The interesting observation is cited⁴⁴ that certain phases in the estrous cycle occur at certain definite times in the diurnal rhythm (maximum estrus in the rat occurs at midnight)."

Fig. 9.5. Apparent diurnal rhythm in fat percentage in morning (a.m.) and evening (p.m.) milk during the lactation period.

9.4: Summary. There is an impressive analogy between diurnal rhythms discussed in this chapter and seasonal rhythms discussed in the preceding chapter, both being ultimately actuated by the sun-earth rhythm; metabolic effects, however different in nature, are exerted not only on plants endowed with chlorophyll but also on animals endowed with eyes. The timing of the rhythmic activity in animals depends on the nature of their visual apparatus, whether they are adopted for relatively dim night light or bright daylight.

The diurnal difference between the metabolic peak and trough is shown

⁴² Detailed curves of the rhythms of muscular activity, respiratory quotients, metabolism, and also descriptions of apparatus are given in the original report, Univ. Missouri Agr. Exp. Sta. Res. Bull. 274.

to be about 25 per cent of the average. The metabolic rhythm reflects activity, feeding, nervous irritability, and related rhythms, although the metabolism was measured during rest.

These rhythms in adults have their ultimate developmental roots in the sun rhythm, transmitted and amplified in the organism by the nature of the visual apparatus, and secondarily in a superimposed social conditioning. The nocturnal rat, for example, develops ingrained habits—conditioned reflexes—of sleeping during the day and feeding, etc., during the night. These reflexes gradually come to include muscle tone, urination, defecation, and intermediate metabolism, including blood composition and perhaps body composition. These rhythms are so persistent that in the rat they cannot be extinguished by a month of continuous light alone, nor by a month of continuous feeding (at 3-hour intervals $\frac{1}{3}$ of the day's maintenance ration) alone, nor by a week of continuous lighting and fasting. But a combination of continuous lighting and continuous feeding ($\frac{1}{3}$ of daily ration every 3 hours) extinguished the metabolic rhythm in about a week.

In addition to their scientific and philosophic interest (from the organismic viewpoint) these rhythms are practically important in studies on the influence of desired conditions on metabolism and related phenomena. Unless the rhythm is taken into consideration, or is extinguished as described in the text, the metabolic (or related activity) difference due to the conditioned diurnal and related rhythms may exceed the metabolic differences caused by the factors under investigation and thus confuse the problem.

In addition to the diurnal rhythms, there are shorter rhythms in the rat, such as Richter's two to four-hour 'spontaneous' rhythms, 3-hour feeding and 'washing-up' rhythms, and numerous digestive, circulatory, respiratory, secretory and excretory rhythms, blood and tissue (especially liver and adrenal) composition, and brain-potential rhythms, all of which influence the metabolic level. There are also longer rhythms. Activities of rats in revolving cages⁴⁶ indicate the presence of 4-day rhythms, and even longer sex- and seasonal-cycle rhythms. There are also several longer body-temperature rhythms in humans. Thus Zucker⁴⁶, Cary⁴⁷, and many others, reported monthly body-temperature rhythms in women, the lowest temperature coinciding with ovulation and increased cervical secretion (Ch. 7).

Chapter 10

Homeostasis and Organismic Theory

In a world struggling for unity, borderlines between the different spheres of human thought become unessential. *Thomas Mann*

Vital mechanisms have one object, preserving constant the internal environment. *Claude Bernard*

About the year 1857 Johannes Müller broke down mentally trying to keep abreast of the literature on physiology. *E. J. K. Menge*

10.1: Introduction. This, like Chapters 1 and 25, is an integrating chapter. It discusses a general principle in biology, analogous to the principle of Le Chatelier¹ or the principle of least action in physical science, or to the principle of sufficient reason in philosophy. We must have binding concepts to give us the feeling of orderliness and keep us from developing a Johannes Müller neurosis. The principle is, in brief, that all organisms and also societies of organisms⁵⁹—epiorganisms (Gerard) or supraorganisms (Emerson)—react to changing conditions in such manner as to maintain constant what Claude Bernard² designated as their “internal environment”.

While the body's powers of adjustment to different conditions have been long known, this knowledge had not become a central principle of physiology—and now of sociology⁵⁹—until Claude Bernard's dramatic formulation, supported by the penetrating contributions of Haldane³, Loeb⁴, Henderson⁵, Cannon⁶, Barcroft⁷, and many others⁸.

Rev.*, 5, 131 (1925). In addition to the above books and reviews, the following papers by Henderson on control of

One of Bernard's generalizations is that the degree of an organism's independence of its environment is proportional to its ability to maintain constant its internal environment: *la fixité du milieu intérieur est la condition de la vie libre*; and that the organism is a closely knit community, the component members of which are organized to keep the internal environment constant in the face of fluctuating external conditions (examples of "physiologic constants": blood pH, body temperature, blood pressure, pulse rate, etc.).

We shall employ Cannon's designation⁶ *homeostasis* to describe this principle, this tendency to maintain a "steady state" (*homeo* from the Greek, like or similar; *homoio*, the same).

Homeostasis, the integrated cooperation of all the organs and systems in the body—nervous, endocrine, circulatory, excretory, digestive, and so on—in the maintenance of a "steady state" equilibrium may be considered as one aspect of what is often referred to as organicism⁹, holism¹⁰, gestalt¹¹, and related concepts including, on other planes, perhaps dialectic materialism¹², multiple causation, and so on¹³.

While some phases of adaptation of organism or supraorganism may be considered as special cases of the theorem of Le Chatelier, formulated for non-living systems, homeostasis is reserved for biologic (and sociologic in this book) changes which do not necessarily occur in the same direction, as they would in a non-living system. Thus changing environmental temperature does not necessarily change body temperature but sets in motion thermo-

acidity are classics: "Equilibrium in solution of phosphates," *Am. J. Physiol.*, **15**, 257 (1906); "Neutrality equilibrium in blood and protoplasm," *J. Biol. F., "Physiology of the nervous system," 1938.

regulatory apparatus to counteract the external change (Ch. 11). Administration of thyroxine to normal individuals does not necessarily increase the metabolic rate, but sets in motion mechanisms for suppression of the body's own thyroxine production (Ch. 7). Reducing oxygen pressure in the air (by climbing a mountain, or in a low-pressure chamber) does not necessarily reduce the oxygen supply to the cells but sets in motion regulatory changes (such as increasing the hemoglobin concentration in blood and other oxygen-carrying mechanisms and—the latest observation—probably increases the concentration of the oxidation catalysts in the body as indicated, for example, by increased excretion—and therefore production—of ascorbic acid in rats on placing them in a low-pressure chamber). Biologic reactions are, evidently, not always explicable on the customary physical or chemical levels (Ch. 16) but on unique *organizational* levels which may not be present in non-living systems. This appears to be recognized as indicated by the following remarks: life is not a characteristic of atoms, molecules, or genes as such, but of a certain organization of the parts of the living organism (E. G. Conklin); the laws of physiology are laws of *organization* (Claude Bernard); physiology is concerned with *sociological* laws, laws of *organization and adaptation* (A. Carrel); the unique problem of physiology is to discover the *relatedness* to one another of the details of structure and function (J. S. Haldane). Darwin has said that evolution is change in form in successive generations *in response* to certain influential factors in the environment.

The concept of homeostasis, especially if it is extended to include societies of organisms as well as individuals, has very far-reaching implications. Indeed, every one of the preceding and following chapters is an illustration of the effectiveness of homeostasis. Thus the following chapter is concerned with homeothermy, the homeostasis of body temperature. Chapter 24 deals with homeostasis in muscular work, that is, the maintenance of a constant level of oxygen and carbon dioxide in the blood in the face of greatly increased oxygen consumption and carbon dioxide production during heavy muscular exercise. Chapters 13 to 15 discuss the homeostasis of metabolism in relation to surface area and to change in form. Chapter 17 is concerned with homeostasis in relation to the ratio of surface area and of strength of the supporting structures to increase in body weight. Chapter 16 deals with the homeostasis of growth: growth proceeds as if the "normal" condition were that represented by the mature size, and the rate of growth tends to be proportional to the distance from the mature size. Chapter 18, on senescence, is concerned with failing homeostasis; and so on, as illustrated by some of the following sections which could be expanded indefinitely.

Pathology may be considered as the study of attempts to maintain homeostasis under conditions of injury. When injury occurs, processes are set in motion to correct it. The tendency to wound healing is, indeed, so great that we pay little attention to it. Even a heart afflicted with coronary sclerosis

(Ch. 18) may function for many years by various compensations, even to the extent of establishing new collateral circulatory vessels to take over the functions of the sclerotic ones. Reproduction of the organism as a whole, as of its constituent cells, may be considered as a compensatory, or homeostatic, mechanism against senescence, maintaining constant the internal social environment in spite of the aging of its constituent members.

The study of homeostasis is, then, the analysis of factors that maintain an advantageous dynamic steady state in biologic systems in the face of conditions that oppose it.

Let us discuss a few illustrative homeostatic mechanisms in detail. In the interest of simplicity each of the following sections is devoted to a different homeostatic mechanism. These mechanisms do not, however, necessarily function independently.

10.2: Body-weight regulation¹⁴. Some readers may recall that their body weight had not changed as much as five pounds over many years, in spite of widely differing conditions of life. Some may also recall the difficulties encountered in attempting to increase or to decrease body weight. The body appears to have automatic regulatory, or homeostatic, mechanisms stronger than purposive resolves to change body weight. Two or three of these mechanisms have been investigated.

One, the decline in digestibility, metabolizability, and assimilability (or increased losses in feces, urine, and heat increment of feeding, or *SDA*) has been discussed (Ch. 5). The more food consumed, the less the nutritive utilization per unit food; conversely, the less food consumed (within certain limits), the higher the utilization per unit food.

Then, too, the higher the food intake, the higher the body weight and, therefore, the greater the proportion of the food that goes to maintain the body; conversely, the lower the food intake and the lower the body weight, the less it costs to maintain the body. In brief, the dietary maintenance tax is adjusted to the dietary input; when placed on a reducing diet the organism becomes more economical, thus counteracting weight reduction; on an abundant diet, the organism becomes more and more extravagant, counteracting undue fattening. The body persists in maintaining its "normal" weight.

Our colleague Addison Gulick¹⁵, characterized by a spare or non-fattening type of "normality", reported in a dramatic manner his strenuous but relatively unsuccessful attempts to gain weight. Gulick "explained" his unsuccessful attempts to gain weight by referring to "spendthrift oxidation

¹⁴ For a recent discussion of the physiologic mechanisms adjusting intake to output, or gains to losses, of body weight, including water, energy, and nitrogen, see Gasnier, A., and Mayer, A., *Ann. Physiol. Physicochim. biol.*, **15**, 145, (1939) (nature and number of regulatory mechanisms); p. 157 (nutritional regulatory mechanisms in the rabbit); p. 186 (regulatory mechanisms of metabolic intensity); p. 195 (breed differences in rabbits); p. 210 (individual differences).

¹⁵ Gulick, A., *Am. J. Physiol.*, **60**, 371 (1922).

during overnourishment" and "economical oxidation during undernourishment".

Anderson and Lusk¹⁶ investigated the efficiency of a dog working under various conditions of food supply. The dog showed greater energy expense when in an overnourished than in a spare condition. Zuntz and Loewy¹⁷ reported 10 and 16 per cent reductions in their basal energy metabolism when placed on the spare German war diet. Benedict¹⁸ and associates reported 20 per cent reduction in basal energy metabolism in young men on a reduced diet involving a loss of 130 g nitrogen.

All in all, the body has very effective automatic mechanisms to prevent interference by purposive meddlers with its normal, that is, its hereditary, weight.

The homeostatic regulation of body weight is evidently of great agricultural importance. High feeding accelerates the fattening process, but it occurs at a greatly increased energy cost; conversely, the leaner the animal at the beginning of a fattening trial the more economic its gains. In general, the economy of gain tends to be proportional to the distance from the "finished condition" (Chs. 5 and 22).

Though we are not here concerned with detailed causal mechanisms, it may be noted that the immediate hunger mechanism was shown by Cannon¹⁹ and by Carlson²⁰ to consist of contractions of the stomach walls. The contraction *hunger* pain is reinforced by *appetite*, psychic longing for the remembered sensation of feeding.

Bulato and Carlson²¹ reported that hunger contractions may be produced at will by reducing the blood sugar by insulin injection, indicating that reduction of blood sugar produces the stomach contractions. There is no doubt that food consumption and weight gains are greatly increased by administration of insulin in proper form (protamine zinc insulin)²². However, it has not been proved that the normal hunger sensations are caused by lowering the blood-sugar level. But whatever the mechanism, it is effective in maintaining the body at its hereditary weight level.

10.3: Body-water regulation²³. The fat-free body of cattle contains about 70 per cent water in adults, 90 per cent in the early prenatal period of growth. If the fat is included, the water percentage tends to vary inversely with the fat content, since muscle contains 75 per cent water, whereas the fat depots contain only 6 to 20 per cent. The early embryo, which has little fat, contains²⁴ up to perhaps 90 per cent water, while the very fat mature steer may contain²⁴ but 40 per cent water. The various constituents differ in their water content: 99.5 per cent in saliva; 99 per cent in cerebrospinal fluid; 85 per cent in brain gray matter, 68 per cent in brain white matter; 79 per cent in blood; 75 per cent in muscle; 72 per cent in skin; 60 per cent in bone.

Water is being continuously lost through kidneys, alimentary tract, exhaled air and skin. These losses are made good by the automatic thirst mechanism, just as losses in body weight are made good by the hunger mechanism.

When excess water is ingested, the body keeps this water from diluting its internal environment by excretion and by storing it in the muscles and skin which constitute water reservoirs. Thus Haldane and Priestly²⁵ reported that of 5 liters water taken between 10:45 and 1:15 p.m., 3.2 liters were excreted in the urine by 3 p.m. Apparently none of the remaining water in the body (equivalent to 40 per cent of the blood volume) was found in the blood. There is considerable evidence that the muscle and skin store the excess water temporarily.

Adolph⁸ reported that the rate of water excretion is proportional to its excess above the normal level and the rate of water intake is proportional to its deficit below the normal water level.

10.4: Carbohydrate-level regulation²⁶. Man does not tolerate a decline in blood-sugar level below about 80 or 70 mg per cent, and if it rises above 160 mg per cent the blood sugar spills over into the urine. The blood sugar in post-absorptive condition is normally 90 to 100 mg per cent, and after a meal about 130 mg per cent. How does the body regulate the blood-sugar concentration within these narrow limits, considering the large quantities of sugar thrown into the blood after a substantial meal, oxidized during heavy muscular exercise, or tapped off during milk production?

Claude Bernard's researches on the blood-sugar level led to his generalization at the head of this chapter. Bernard's conclusion, amply substantiated, is that the excess glucose is converted into insoluble glycogen and fat. The liver is the major glycogen-storing organ, accounting for from one-fourth to over one-half the total body glycogen; the remainder is distributed in the muscles. The glycogen is reconverted to glucose and fed back to the blood at a rate required to maintain the blood-glucose constant. Insulin (from the islets of Langerhans of the pancreas) is the major hormone involved in this conversion. The blood-sugar level is also regulated by the pituitary (glycotropic hormone), thyroid, and kidney. In addition, the nervous system is involved, by serving as medium of transmission and communication for the bodily needs. The sympathoadrenal system is involved in sugar mobilization in emergencies (see Cannon⁴⁹).

While excess sugar in the blood does not produce important subjective symptoms, blood-sugar deficiency leads to feelings ranging from hunger through nervousness and weakness, to convulsions following an excessive dose of insulin injection (insulin or hypoglycemic reactions). Objective symptoms are pallor, rapid pulse, dilated pupils, profuse sweating, and convulsions. The brain obtains its energy perhaps exclusively from sugar^{27, 28}. For this reason, in part, sugar deficiency in blood, for example, insulin hypoglycemia, leads to serious nervous disturbances²⁹ (Sect. 20.2).

Blood-sugar regulation declines with age following 30 or 40 years³⁰, perhaps because of defective glycogen storage in the liver³¹.

10.5: Calcium-level regulation The parathyroid hormone (parathormone) is the principal regulator of calcium-metabolism³² (Ch. 7), analogous to insulin, the principal carbohydrate-metabolism regulator. The percentage range of the calcium level in blood (9 to 12 mg per cent plasma) is of the same order as the percentage range of glucose in the blood (80 to 130 mg per cent). There is the additional limitation that the product of calcium and phosphate ions should be constant (in serum the product of Ca and of P in mg is about 36 and the Ca/P ratio between 1 and 2). In other words, the proper functioning of calcium metabolism is also dependent on a certain phosphate³³ concentration, and it might be added, on a certain concentration of parathyroid hormones, vitamin D, and phosphatase enzyme.

³³ Rickets is often the result of phosphorus deficiency, as also of calcium deficiency.

The equilibrium between calcium ion on one hand and insoluble bone $[\text{CaCO}_3 \cdot 2 \text{ to } 3\text{Ca}_3(\text{PO}_4)_2]$ on the other, is analogous to the equilibrium between blood sugar and glycogen.

Just as hypoglycemia affects the nervous system (mostly the cortical function), so hypocalcemia affects the nervous system (mostly the autonomic and peripheral nervous systems). Milk fever (in dairy cattle) is a familiar agricultural example of hypocalcemia.

10.6: Fat-level regulation³⁴. The blood contains lipoids in the form of total fatty acids or "total lipid" 300 to 500 mg per cent; cholesterol esters 150 to 190 mg per cent; lipid phosphorus (lecithin) 12 to 14 mg per cent; or phospholipid about 140 mg per cent (in plasma) to 420 mg (in corpuscles). However, very much higher values were recorded in essential hyperlipemia³⁵. Ingestion of a meal of fat results in "alimentary lipemia", associated with a rise of fat in blood to 2 or 3 per cent.

As sugar or calcium concentration remain nearly constant by storing or drawing on glycogen or bone, so the lipoids remain roughly constant by storing fat in various fat depots when there is excess of it, and drawing on these fat depots when there is scarcity of food.

The physiologic control of lipid transport has been investigated most extensively by Bloor³⁴. As a calcium hexose monophosphate is the important intermediary in calcium metabolism and calcium homeostasy, so lecithin, also a phosphorus-containing substance³⁶, appears to be the important intermediary in lipid homeostasy. It was noted (pp. 128 and 133) that lecithin (or choline) deficiency leads to the formation of fatty livers and "cholesterol livers"³⁷.

10.7: Oxygen and acid level regulation. The process of living involves the consumption of enormous quantities of oxygen and production of equivalent quantities of acids (carbonic, sulfuric, phosphoric, etc.). Yet both oxygen and acid levels deviate insignificantly from the "normal" level even during

³⁴ Bloor, W. R., *Physiol. Rev.*, **2**, 107 (1922); *Chem. Rev.*, **2**, 243 (1925); "Harvey Lectures", p. 39, 1923-24, and more recent reviews in *Ann. Rev. Biochem.*; "Biochemistry of Fatty Acids," Reinhold, 1943.

³⁵ Bernstein, S. S., *et al.*, "A child with essential hyperlipemia," *J. Pediatrics*, **14**, 570 (1939), cited the following data, mg 100 cc blood.

	Total lipids		Phospho-lipids		Neutral fat		Free cholesterol		Cholesterol esters	
	Plasma	Erythrocytes	Plasma	Corpuscles	Plasma	Corpuscles	Plasma	Corpuscles	Plasma	Corpuscles
Normal 6-yr old	452	418	140	240	94	44	33	99	184	34
The hyperlipimid child	3100-4200	650-760	440-520	480	2100-3200	50-450	130-200	80-95	430-700	80-95

³⁶ For the formula of lecithin, see page 128.

³⁷ Best, C. H., and Ridout, J. H., *Ann. Rev. Biochem.*, **8**, 349 (1939).

muscular exercise, when the oxygen consumption and carbonic acid production may increase ten-fold (Ch. 24). This constancy of internal environment is brought about by several mechanisms, from increased ventilation rate and circulation rate (Ch. 24) to increased hemoglobin concentration. Thus ascending Mount Everest about 20,000 feet, where the oxygen pressure is 50 per cent of that at sea level, the blood hemoglobin may increase from 4 million cells/cc to over 8 million. Moreover, a hemoglobin unit in high-mountain dwellers can carry more oxygen, as illustrated by the following data from Dill³⁸ on high-mountain dwellers.

	Vicuna - (high-mountain dweller)	Man	Domestic Sheep
Volume % arterial O ₂	18.0	14.4	8.4
Volume % venous O ₂	4.0	2.4	1.0
Difference	14.0	12.0	7.4

Then, too, under sudden demand for oxygen the blood stored in the spleen and liver is released to help with the oxygen transport. Barcroft³⁹ reported that the spleen of a dog was reduced to $\frac{1}{4}$ normal size when the dog was set to chase a cat. Scheunert and Krzywaneck⁴⁰ reported increased blood counts in horses during exercise. Rein⁴¹ reported that the liver released 25 per cent of its blood under the influence of adrenaline. In brief, exercise and other conditions which involve increased oxygen use are associated with increased hemoglobin concentration.

It is interesting to recall that in the later stages of gestation fetal growth proceeds at an increasingly relative faster rate than the placenta, resulting in decreased oxygen supply to the fetus. The blood picture of the new-born shows the effects. This prompted the remark (by Barcroft?) that during the last stages of gestation the embryo lives in a Mount Everest atmosphere and is acclimated to it. For this reason, in part, new-born and very young animals have very high hemoglobin concentration and, in general, tolerate anoxia very much better than older ones (Ch. 14).

The exceptional ability of whales, seals, and beavers to remain submerged for half an hour depends (Ch. 24) on these homeostatic reserves: large blood volume, high hemoglobin concentration, the ability to go into great oxygen debt, and especially the ability to shunt the blood (which carries the oxygen) to the central nervous system (most sensitive to oxygen want) from the other tissues, those less sensitive to oxygen want. Anoxia is also associated with

³⁸ Dill, D. B., "Life, heat, and altitude," Cambridge, Mass., 1938. Altitudes and air pressures: Mount Everest having an altitude of about 29,000 feet, has an air pressure which is about 35 per cent of sea-level pressure; Pikes Peak, 13,000 feet high, about 60 per cent sea-level pressure; Mexico City or Santa Fé about 8,000 feet, about 78 per cent sea-level pressure; Denver, about 5,000 feet, about 83 per cent sea-level pressure. Hall, F. G., Dill, D. B., and Barron, E. S. G., *J. Cellular and Comp. Physiol.*, **8**, 301 (1936).

lowered body temperature and, therefore, reduced metabolism and depressed oxygen need.

Since lack of oxygen and lack of glucose have the same end effect on brain metabolism, the nervous symptoms described for hypoglycemia also hold for anoxia⁴².

The mechanism of blood-acidity regulation was worked out chiefly by Henderson^{43, 5}. The blood pH ranges only⁴⁴ from 7.30 to 7.45. Even feeding sulfuric acid (over a liter a day of N H₂SO₄ to hogs⁴⁵) did not change it.

The maintenance of constant pH of the blood is accomplished by (1) preliminary neutralization by the blood buffers (bicarbonates, phosphates, hemoglobin, and also by ammonia), (2) excretion of the volatile acids (CO₂) by the lungs, and (3) excretion of the non-volatile acid by the kidneys.

10.8: Neuro-endocrine homeostasis. We have seen (Ch. 7) that if the metabolic hormone thyroxine is injected, the body "tries" to keep the metabolic level constant by reducing its own production of thyroxine. Similarly, if the sex hormone estrogen is injected, the animal "tries" to maintain its normal sex activity level by reducing the production of its own estrogen. Both of the controls are carried out by way of the pituitary, by depressing the production of thyrotropic and gonadotropic hormones respectively. The same mechanism is employed for many other hormones controlled by the pituitary.

Dairymen know that milking stimulates and cessation of milking depresses milk production. Now milk production is dependent on pituitary lactogenic hormone production, and it appears⁴⁶ that suckling stimulates it, obviously by a nervous path. The closely related maternal reflexes are even more intimately dependent on the central nervous system, including the higher brain centers⁴⁷.

The dietary control of insulin production is interesting. On heavy feeding, the islets of Langerhans hypertrophy, producing more insulin to take care of the excess sugar. However, this often sets up a vicious cycle: the more food, the greater the hyperinsulinism and the greater the hyperinsulinism the greater the desire for food. This leads to obesity and frequent degeneration of the islets of Langerhans due to overwork⁴⁸. Here we have a type of homeostasis which by its immediate correction leads to ultimate failure.

There are other examples of the same type. Thus strong emotions lead to nerve excitation (parasympathetic, vagi, sacral) and production of excessive amounts of acetylcholine, sympathin, histamine, adrenaline, and so on favoring the overcoming of the immediate emergency but often with unfavorable long-range effects (Ch. 18) on the circulatory and digestive systems. Exophthalmic goiter is attributed by Crile (Ch. 18) to over-excitement.

A familiar example of the effect of nervous stimuli on endocrine activity, which has a homeostatic basis, is the mobilization of sugar (hyperglycemia) during emergency to furnish the energy for the forthcoming effort; if the effort does not materialize on a physical plane (as in the case of a spectator at a foot-ball game who does not himself fight although emotionally geared thereto), the sugar is eliminated by the kidney, constituting the well-known emotional glycosuria, thus keeping the blood sugar level constant (Cannon's emergency theory⁴⁹, see Sect. 7.3.2B).

Some emotions become habitual, chronic, "structured", or conditioned, such as those investigated by Pavlov⁵⁰. These are of great agricultural as well as social importance. Good animal husbandmen appreciate the importance of gentle treatment of their animals, and are aware of the unpleasant conditioned reflexes, or habits, that may develop, especially in horses and dairy cattle. As Mark Twain has said, habit is habit, not to be flung out of the window by any man.

Rapid salt loss due to any one of many causes, such as adrenalectomy⁵¹, diabetes insipidus⁵², or sweating is associated with corresponding craving for salt⁵³. On the other hand, extreme salt consumption is often a diagnostic symptom of adrenal and related diseases. Indeed, it has been suggested that taste thresholds may serve as delicate indices of nutritional deficiencies⁵⁴.

Parathyroidectomy, which disturbs calcium metabolism, is associated with greater (four-fold) calcium (lactate) intake⁵⁵. In the absence of calcium more magnesium and even strontium salts are consumed. During pregnancy and lactation protein and mineral (but not carbohydrate) intake is increased⁵⁶.

Vitamin B is essential for carbohydrate oxidation; hence the aversion for carbohydrate (and protein) and craving for yeast on a vitamin B-deficient diet^{56, 57}. However, this homeostatic mechanism does not function precisely.

Thus chickens do not differentiate between riboflavin-rich and riboflavin-poor diets even if they are riboflavin-starved⁵⁷. Many other examples could be cited⁵⁸.

Appetite, then, appears to be in many cases, but not in all, an important guide to "nutritional wisdom" or homeostasis, provided that it is not conditioned adversely in early life. The wide popularity of "sweets" and white bread may be the result of early conditioning by a wrong "psychodietetics". It is interesting to note that such animals as dairy cattle and high-laying fowl raised under relatively artificial systems rather lack nutritional wisdom, and the same is true of children (Sect. 20.5).

10.9: Social homeostasis.⁵⁹ A multi-cellular organism may be viewed as a community of individual cells specialized to perform various functions for the community as well as for carrying out their own basic metabolic or life processes. Such a viewpoint suggests an analogy between an *individual* multi-cellular organism, for example an ant, termite, or bee, and a society of organisms, or supraorganism, for example, a *colony* of ants, termites, or bees. The multicellular individual termite is derived from a single egg cell. The cells of the individual differentiate, by virtue of their positions in the body, into the various specialized cells and tissues. Similarly, the colony of termites or bees is derived from virtually a single egg cell, the individuals of which differentiate, by different feeding methods and other conditions, into various specialized individuals—workers, soldiers, drones, queens, and so on.

In some species at some time it is indeed impossible to distinguish between a multi-cellular individual and a closely integrated group of individuals. Not only are the two categories alike in being composed of the same ultimate substances, carrying on the same metabolic processes, having similar adaptive mechanisms, but both are stages in the evolution of ever larger and more integrated "orgs". It will be shown (Chs. 16 and 19) that the age curves of growth of individuals, such as rats or pumpkins, are so similar to the time curves of growth of populations (of yeast, bacteria, flies, men) that all the curves can be made to coincide.

This analogy between the individual organism and society of organisms extends to social homeostasis, of which social insects (such as termites, ants, bees, and so on) furnish striking examples on one organizational level. But one may cite examples of homeostasis on many different levels and in different categories, indicated by the following illustrations.

The reproductive function attains peak activity when growth approaches its end (Ch. 16), that is, when the individual organism begins to get old. Sexual virility may thus be said, figuratively, to coincide with approaching individual senility (Ch. 18). The lawn grass goes to seed most readily when individual life is threatened and on the decline (as in drought, etc.). Reproduction of the individual may thus be viewed as a phase of social homeostasis. By reproduction the "internal environment" of the social organism is kept constant in spite of the aging and dying of its constituent members. Reproduction is a social homeostatic mechanism.

The reproductive process (Ch. 7) is extremely complex and, needless to say, the individual plant or animal does not foresee the social-preservation, or sociocentric, "purpose" of its reproductive drive, just as it does not foresee the individual-preservation,

⁵⁸ Cf. Jones, H. M., *J. Am. Med. Assn.*, **115**, 274 (1940).

⁵⁹ Cf. Cannon, W. B., "The body physiologic and the body politic," *Science*, **93**, 1 (1941). Gerard^a, and the other essays in Redfield^a. Brody, S., "Science and Social Wisdom", *Sc. Monthly*, **59**, 203 1944.

or individuocentric, "purpose" of its hunger and thirst drives. But the ultimate functional aim appears to be to maintain constant the "internal environment" of the social and individual organisms respectively.

The homeostatic mechanisms appear to evolve to ever finer organizational levels. Thus (Ch. 8) reproduction is adjusted, in the social interest, to function in such seasons of the year as will give the new-born animal the best opportunity for survival.

The development, in the most evolved animals (mammals), of the uterus and of mammary methods of raising the young is another illustration of the increased perfection of social homeostasis with advancing evolution. Instead of dropping the unfertilized eggs in the ocean as a fish does, the highly evolved mammal houses and nurtures the young in an especially evolved body cavity; then, after birth, gradually bridges the young to independent life by feeding it with the special mammary secretion. The dairy industry is, of course, based on the exploitation of this evolutionary mammary development.

This type of reproductive method develops family life. Family life is also strong in many bird species, especially those like pigeons, which produce "crop milk", and as previously noted on a different organizational level, in social insects. But it is, perhaps, on the highest level in mammals, particularly in man, who is distinguished from other mammals by a higher level of consciousness and by the ability to raise children of different ages simultaneously. Thus a special type of social life evolves, leading to the development of the uniquely human social characteristics of patience, forbearance, and charity on the part of the older and stronger children toward the younger and weaker. These newly evolved characteristics may be called moral or ethical, and are destined to play an ever greater part in the evolution of human social life if the human species is to survive.

In man we see the family idea, with its higher level of conscious homeostasis, develop into ever larger aggregations—tribe, clan, nation, and finally, perhaps, a world federation. These broader human aggregations are made possible by the unique human ability for abstract thinking and communication in symbolic terms—language. By such communication men learned to recognize, in an impersonal way, the relatedness of all mankind. These unique recognition qualities in man have a structural basis in his nervous system. Primitive animals and primitive functions in higher animals are controlled by the autonomic nervous system concerned primarily with adjustment between organs within the individuals; the higher functions in the more evolved animals are controlled by the central nervous system, especially by the brain and more particularly by the fore-brain, the cerebral cortex, concerned with adjustment of the organisms as a whole to distant environment. The development of the brain reached enormous proportions in man with correspondingly far-reaching recognition qualities. The brain weight (by no means the only index of high development) in a 150-lb man is over three pounds, whereas that in 1500-lb cattle is less than one pound (Ch. 17). Indeed, with the exception of the whale and elephant, man has the largest absolute brain. (Fig. 10.1).

The extraordinary brain development in man and his unique abstract or symbolic method of communication and preservation of accumulated knowledge, introduced a new factor in evolution, not dependent exclusively on genetic modification. The genetic make-up of man is certainly the same today as it was 200 years ago—and perhaps 20,000 years ago—and yet what transformations have occurred in human life, due to the development of science! Indeed, the automobile, telephone, electric light, radio, hydroelectric power, airplane, submarine, bombers, poison gases, not to speak of the gang plow and tractor, cream separator, combine harvester, chemical fertilizers, immune sera, anti-toxins, prefabricated houses, and so on, developed within the writer's memory. The evolution and integration of human society has thus become disengaged from genetic change, although it may lead to *purposive* genetic change. The future course

of the evolution of man is in the hands of man himself, and it is difficult to predict what he will do with himself.

His future becomes ever more unpredictable by the very development of his abstract methods of thinking and communicating and by his science and invention. Thus an abstract idea, perhaps biologically destructive and therefore humanly senseless, if rationalized in words which appeal to emotional residues, may precipitate a world war and all but destroy man and his works. World War I is said to have cost in goods the equivalent of 340 billion dollars and some 33 million human lives in military and civilian casualties. The present better and bigger World War II, it is estimated, will cost at least the equivalent of 1000 billion dollars in goods and 50 million in military and civilian casualties. And who can predict what the third world war will cost and whether human society will react to these changes "so as to bring itself to normal"?

This calls attention to a curious characteristic of the average man: that while he thinks himself logical enough to have "common sense", he is often devoid of it. It

Fig. 10.1 The relation between the average brain weight of mature man and of the average brain weight of mature mammals of other non-anthropoid species ranging from mice to whales. Man's brain weight is almost as large as the elephant's.

took not the "common sense" of the average, but the uncommon sense of the rare "impractical" scientist to demonstrate that the earth is not flat, and so on for nearly every astronomic and other scientific discovery. Words, or language, may be used for illogical as well as for logical ends. This is generally known to psychologists.

Most of us are, indeed, familiar with "psychologic warfare", the "war of nerves",⁶⁰ and with the concept of "rationalization". Like other human inventions, language may be used for good or evil, for healing or for wounding, for peace or for war^{60, 61}.

⁶⁰ For psychology and propaganda as war weapons, see among others, Cantrill, H., "The Psychology of Social Movements," New York, 1941. Pope, A. P. (Chairman), "German Psychological Warfare," Committee for National Morale, 51 E. 42nd St., New York, 1941. Hackett, F., "What Mein Kampf means for America," New York, 1941.

⁶¹ There is a growing literature on non-logical thinking. For the most elaborate book on non-logical patterns of human action, one which may have encouraged the rise of Fascism and Nazism, see Vilfredo Pareto, "Traité de sociologie générale," Paris, 1917, or Pareto, V., "The mind and society," New York, 1935. For more recent books, see among others, Korzybski, A., "Science and Sanity," The Science Press, 1933; Baynes,

Social homeostasis in man, as it relates to the balance between peace and war, appears to be roughly as follows^{62, 63}. Animal evolution, including that of man, involves two opposing drives: (1) an egoistic (strutting, fighting, various "pecking-orders"⁶², and other forms of egocentric self-aggrandizement) and (2) an altruistic (sex, parenthood, family, flock, herd, tribe, clan, nation, and perhaps supnation, and other forms of sociocentric activity).

Allee⁶² and colleagues⁸ emphasized the relatively greater altruistic than egoistic drives in evolution; otherwise the more highly evolved animals and animal societies could not have evolved because the animals would have destroyed each other under the compulsion of the self-aggrandizement drive. This may have occurred in some species that developed particularly effective fighting weapons (as saber teeth in the saber-tooth tiger), and this may be the case in contemporary man with his scientific weapons⁶².

Paralleling the development of man's increasing powers for destructive warfare, as a result of his thinking on abstract levels, there also developed in all human civilizations a unique altruistic power on an abstract level, one which goes under the general name of "religion". Omitting for the present purpose the ritual and supernatural aspects of religion (without, however, minimizing their importance as carriers of altruistic action), its basic features are humility, counteracting the strutting and related self-aggrandizement drives, and neighborliness or the Golden Rule, counteracting the fighting and related pugnacious drives.

These two basic features of all religions, no matter how worded, are generally accepted not only by the leaders of conventional religious sects but also by philosophers and biologists who have outgrown the stage of so-called conflict between science and religion⁶⁴. In brief, it appears that religion is a social homeostatic phenomenon evolved on a characteristically human level of symbolic thought, as war is evolved on a characteristically human level of abstraction. This homeostatic mechanism, religion, has not been functioning well in recent years, and it is suggested that it be investigated on the characteristically human level, scientifically, to set it aright, so as to serve its function in keeping in check destructive forces in the form of world wars. The greatest immediate need seems to be the development of methods for selecting leaders who will utilize the tools of science, which grow cumulatively ever more powerful, for peaceful construction rather than for warlike destruction.

10.10: Notes on organismic or field theory and on research methods. The living body's building stones, the electrons, protons, atoms, and molecules, are no different from those in non-living systems. But in virtue of its peculiar

⁶⁴ A. N. Whitehead, philosopher and mathematician, writes: "Science is concerned with the conditions which regulate physical phenomena, whereas religion contemplates moral and aesthetic values. On one side there is the law of gravitation; on the other, the contemplation of the beauty of holiness". W. C. Allee, a biologist, states: "To me 'God' is a . . . name for the personification of all the best that the human race has been able to think and do and of all the beauty we have created, together with all the natural beauty we can appreciate; and religion as . . . unselfish living and honest thinking. . . ." To the author⁶⁵, religion seems best defined by: the consecrated devotion to the values and/or to the faiths which seem to promote the best interest of humanity.

organization the *organism as a whole* is in a different category from that of non-living systems⁶⁵. In general, the biological form of order is different from those found in non-biologic systems—"it is a new dialectic order"⁶⁶.

The organismic or field hypothesis in biology⁶⁷ is similar in intent to the field theory of the newer physics. Just as the "field" in physics is an electromagnetic integrative process, so the "field" in biology is an integrative process binding the many components into a whole, perhaps at different levels (Ch. 17). The characteristic of the *field pattern* as defined by Weiss is that *it tends to be restored on disturbance*, which is also the definition of homeostasis.

The existence of a stable field pattern during growth and development may be demonstrated experimentally. It was pointed out (Chs. 7 and 16) that an egg, or even a gastrula, may be divided into several parts, and that each part may develop into a complete individual. This indicates that the destinies of the parts of the embryo are also shaped by the environment, and by the field pattern which restores itself after being cut up into parts. This was substantiated in another way by Spemann, who demonstrated that prior to the gastrula stage head formation may be induced in either head or tail region under the influence of a hormone-like head organizer, or under the influence of another field, by transplantation (see Sect. 7.8.2).

In a later stage, however, tissues no longer respond indiscriminately to *organizers*; each tissue develops a characteristic response, and the formation of head or tail depends not only on the nature of the organizer, but also on that of the tissue competence. Thus, at first, any part of the neurula could develop gills; later only a special gill area is capable of developing gills.

These ideas on individual (ontogenetic) loss of plasticity with advancing age may be extended to species (phylogenetic) loss of plasticity with advancing evolution. Primitive organisms have greater potentialities for diversification than more evolved forms; a given species is such not because it was evolved from a given evolutionary predecessor but because, in addition to the proper potentialities of the predecessor for the given type of evolution, the predecessors were subjected to environmental influences and field structures which acted as "evocators" or "organizers" for the given evolutionary course of the species (see Sect. 7.8.1).

As growth proceeds and the tissues and organs become ever more specialized, they necessarily become further separated from one another in space and time because of the differential rate of aging of tissues and organs. The various specialized organs are, however, closely integrated by organismic devices, such as the nervous, circulatory, endocrine and other systems.

What was said about ontogenetic specialization and spatial separation is applicable to phylogenetic specialization and spatial separation, with con-

⁶⁵ Frank, L. K., *Philosophy of Science*, 2, 210 (1935).

⁶⁷ Burr, H. S., and Northrop, F. S. C., "The electro-dynamic theory of life," *Quart. Rev. Biol.*, 10, 322 (1935); *Growth*, 1, 78 (1937).

sequent greater need of integration by increasingly complex organismic devices.

Schmalhausen⁶⁸ remarked that the greater the degree of specialization of parts of an organism, the greater the degree of their interdependence and the higher the integration level. High specialization of structures and functions must necessarily be associated with high organismic integration if the organism is to survive. The same idea was expressed by many others.

Since a highly specialized organism is a closely interrelated field-structure, it follows that when a tissue, cell, or molecule is removed from its field, it no longer exhibits its normal "organismic" characteristics⁶⁵. Consequently, the usual method of experimental investigation of growth is in a sense artificial because it separates the unified growth process. Experimentally, however, the whole is often best approached through a study of its parts. The study of parts often leads to valuable intellectual syntheses of the whole⁶⁹. Such, in fact, is the history of many scientific syntheses. The configuration of the atom as a whole was learned by splitting it into parts. The discovery of many vitamins and hormones and of their interrelations was accomplished in some respects by artificial "split-field" methods. The "split-field" method of research may be philosophically objectionable, but in practice it is unavoidable.

Other methodological problems have been raised since the development of the field, organismic, and relativity concepts, indicated by the following illustrations.

One of these is known as the *principle of uncertainty* or *indeterminacy* formulated by Heisenberg⁷⁰ in 1926, to the effect that the observed system is altered by the observation of the observer.

This Heisenberg Principle was formulated for small-scale (e.g., motion of electron) events. To illustrate, an electron is observed with the aid of the light of another electron. This light influences to an unknown extent the behavior of the observed electron, so that it is impossible to observe a given electron unaffected by the observation light. That is to say, the observer is a part of the observed system, and the measured object is altered by the act of measurement itself.

This principle, based on small-scale observations, may be extended to large-scale observations whenever the act of observation alters the measured object. Thus it is not possible to determine the precise chemical constitution of a *living* cell, inasmuch as the attempt of the observer to observe the cell (by chemical analysis) alters the observed system (by killing it). Of course, this is rather an extreme example.

The application of Heisenberg's deductions from small-scale events (elec-

⁶⁸ Schmalhausen, I., *Quart. Rev. Biol.*, **14**, 65 (1939).

⁶⁹ Cf. Hopkins, F. G., *Science*, **78**, 219 (1933).

⁷⁰ Heisenberg, W., "The physical principles of quantum theory," Univ. Chicago Press, 1930. Compton, A. H., "The freedom of man," New Haven, 1935.

trons, protons) to large-scale events may be illustrated more cogently by examples from Compton⁷⁰ and Lillie⁷¹. Nerve impulses, electrochemical in nature, are small-scale events, as, for example, those resulting from the impingement of light protons on the eye. The organism acts as a powerful amplifier which sets in motion large-scale events. Consequently, the large-scale end-result may have uncertainties of the same order as the small-scale events.

While the behavior of small-scale events at a given moment is not definitely determined, it obeys the laws of probability. "The quantities which appear in its [quantum mechanics] laws make no claim to describe physical reality but only the probability of the appearance of a particular event" (Einstein). This generalization is in a sense applicable to all measurements and predictions, which is one reason for the use of statistical methods in the analysis of experimental data.

Large-scale uniformities, which constitute the subject matter of scientific laws, may be considered as statistical averages of small-scale or "atomic" diversities. Thus, while it is not possible to predict individual durations of life, yet, judging by the practical success of life insurance companies, it is possible to predict the *average* expectation of life. The immense practical success of science and industry based on scientific laws testifies to the *average* orderliness of events. In view of this evident orderliness, the following unqualified opinion⁷² seems misleading. "The universe is . . . without unity, without continuity, without coherence or orderliness Order, unity, and continuity are human inventions just as truly as are catalogs and encyclopedias Such orderliness as we appear to find . . . seems to be due to our passion for pigeon holes, and it is quite doubtful whether there are such things as laws of nature". The view that the world is an *interrelated* dynamic configuration seems more reasonable. Perhaps the following remark by Hyman Levy represents more nearly the situation: "The world is an enormous interrelated dynamic muddle with intermittent patches of order and sanity".

The problem of uncertainty discussed above leads to the problem of the methodology of mathematical analysis of experimental data.

Now mathematics has two aspects: theoretical, not dependent on reality, and applied, which is very real indeed. The two aspects are illustrated by the following quotations and discussions.

"Mathematics is not science; it is not nature, unless it be in the nature of the mind; it is not concerned with the truth but only with the exactness of the deductive process. Is the formula $50 \times 2 = 100$ true or false? The answer depends on circumstances. It is true when applied, for example, to 50 apples in one basket and 50 in another. It is debatable when applied, for example, to temperature: 100°C is hardly twice 50°C ".—E. Bidwell Wilson.

"Mathematics is a natural science . . . it has its origin in the objective world, of which it studies the spatial and numerical aspects. The law that $2 \times 2 = 4$ is not only a law on paper, but as a mathematical law expresses relations in objective reality, like the law that hydrogen and oxygen form water under proper conditions".—D. J. Struik.

⁷⁰ Lillie, R., *Science*, **46**, 139 (1927).

⁷² Russell, Bertrand, "What I believe," *Nation*, p. 412, 1940.

"One cannot escape the feeling that mathematical formulas have an independent existence and an intelligence of their own . . . that we get more out of them than was originally put into them".—Heinrich Hertz.

"One tries . . . to employ numerical discourse . . . because of the stock of ready-made devices and calculations which were accumulated in the pursuit of mathematics".—Leonard Bloomfield.

For our purposes, the usefulness of mathematics consists in its operational convenience. Mathematics is a lever, as it were, by the use of which unwieldy masses of experimental data are lifted into analytic view. The tremendous progress of the physical sciences in general and of engineering in particular since the Renaissance is in large measure due to applications of the analytic mathematical methods developed during this period. These methods should also prove fruitful in the investigation of motions of biological phenomena, such as growth.

The operational advantages and disadvantages of mathematics are not unlike those of symbolic logic⁷³. Both have the advantages of simplicity, "purity", and isolation. But the advantages of generality, simplicity, purity, and isolation are also disadvantages. A symbolic language isolated from the material world cannot fully represent the complex phenomenal interrelationship of the material world, although it is probable, as indicated, for example, by the groupings of matrix algebra, that the symbolic language of mathematics and logic will develop a broader adequacy reflecting physical reality to a greater extent. Regardless, therefore, of the technical refinements of a mathematical result, its representation of a situation is necessarily inadequate and over-simplified, and must be interpreted in the light of what is called "common sense", that is, judgment in the light of experience.

In connection with the widespread application of the mechanical rules of statistics to biology, Wilson⁷⁴ writes: "I say beware of the mere formal application of probable error to meager statistical material. Your conclusions will almost certainly be wrong. The statistical method, like other methods, is not a substitute for, but a humble aid to the formation of a scientific judgment. Only with this philosophy in mind may we truly hope, with care, to avoid in the main being classed in the superlative category of that oft-cited sequence of liars, damned liars, and statisticians!"

Sets of observations, for example, basal metabolism and body weight (Chs. 13 to 15), are usually related to each other by some equation. The equation may be empirical or rational. There are many degrees of rationality, but the constants of the rational equation should at least have definiteness of meaning. A potential series, such as $Y = a + bX + cX^2 + dX^3 \dots$, is not rational because (1) any continuous set of observations can be represented by such a series if enough terms are chosen, and (2) if one of the terms of the series is omitted, the remaining constants assume different numerical values. This type of equation is, therefore, ambiguous because its terms have no definite, constant, meaning.

An empiric equation, then, may have description value, but does not represent a uniformity of nature. A rational equation, such as the gas law $PV = NRT$, or the gravitational equation $F = G(MM'/d^n)$, represents a certain concept of the phenomenon, perhaps idealized, that is, undisturbed by lesser causes, the constants of which are unambiguously defined. Rational equations often represent the data with less precision than empiric, because of their idealization. On the other hand, a prediction based on a rational equation is more reliable. The distinguishing feature of the rational equation

⁷³ Cf., Neurath, Bohr, Dewey, Russell, Carnap and Morris, "International Encyclopedia of Unified Science. Foundations of the Unity of Science", Vol. 1, No. 1, University of Chicago Press, 1939. Woodger, J. H., "The technique of theory construction," *Id.*, Vol. 2, No. 5.

⁷⁴ Wilson, E. Bidwell, *Science*, 80, 193 (1934); 58, 93 (1923); 63, 289 (1926); 65, 581 (1927).

is not that it represents data with great precision, but that it represents or intends to represent a uniformity or "law" of nature.

Equations frequently have broader significance than the author believes them to have, so that they can represent with equal facility quite different, even contradictory, theories. Likewise, different types of equations may often represent the same phenomenon. There is, therefore, no dividing line between rational and empiric equations except in the author's concept.

In the last analysis, mathematical representations are oversimplified mathematical models, only partial descriptions of a limited portion of a long chain of interrelated events, rather than explanations. This is due to the discrepancy between the necessarily idealized nature of the assumptions for mathematical representation on the one hand and the complexity of the "field" or the process on the other. A mathematical equation represents an isolated relationship while reality is organismic, with complex multi-dimensional ramifications. Rationalism and empiricism are, therefore, relative terms, descriptive of the spirit of the investigator.

Empiric equations are useful for condensing unwieldy tables into a brief formula, for codification (e.g., formulating growth standards), classifications (e.g., with regard to rate of growth and development, variability, correlation, etc.), but not for predicting outside the observed limits. Agriculturists are familiar with the practical usefulness of age and other time "standards" of physical growth, milk production, egg production, wool production, fertility, life expectancy, and so on.

10.11: Summary. This chapter is concerned with a very general principle in biology, designated "homeostasis" by Cannon, which may be called the principle of Claude Bernard for living systems analogous to the principle of Le Chatelier for non-living systems.

Homeostasis, or the principle of Claude Bernard, refers to the regulatory mechanisms which maintain constant the "internal environment" of the organism in the face of changing conditions. Thus the body temperature of man remains constant although the external environmental temperature may range from 0°F to 100°F; high-milking dairy cows gain (from the feed) or lose (into the milk) colossal amounts of minerals, proteins, carbohydrates, and water, yet maintain constant the concentration of these nutrients in the blood; and so on.

Homeostasis is the major manifestation of what is sometimes referred to as the "field" formulated by the "organismic theory" in biology. "Field" refers to the totality of the interactions in the living system with the environment, internal and external. The *living field* pattern of the biologist is analogous to the *electromagnetic field* pattern of the physicist. The behavior of the bodily constituents is determined by the living field structure as a whole in the same sense as the behavior of iron filings or of electric events is determined by the electromagnetic field structure as a whole. This living field pattern has a certain dynamic stability, that is, it tends to restore itself to "normal" by many organismic or homeostatic devices.

These concepts of field, organism, and especially homeostasis, were extended to societies of organisms, especially to their ever finer social integration in the course of evolution; and to certain philosophic aspects in sociology and social

evolution. Human society is apparently in the throes of a transition period due to the unbalanced development of techniques, discussed in the text (also in Ch. 25).

The concepts of field and homeostasis invalidate the concept of "cause" as a one-sided action. Thus many endocrines are stimulated to activity by the pituitary (tropic hormones). But this is not one-sided; the glands which are controlled by the pituitary also control the pituitary. The interrelation is mutual. Moreover, the pituitary is, itself, a part of the total functioning organism, and can function only as the organism keeps it so. Similarly in other realms: high government expenses "cause" high taxes; and high taxes "cause" high government expenses. The interrelation is mutual.

The field concepts of living and non-living systems may be integrated into a more general field concept. There is no sharp dividing line between living and non-living, but they function at different levels, just as within the living category, there are many different levels of organization and function.

The narrow border between living and non-living, at its limit, is indicated by the fact that *crystalline* protein ("non-living") prepared from tobacco-mosaic virus has the ability to propropagate itself ("living")⁷⁵. The bacteriophage⁷⁶ is in the same category.

During growth and development the "field" is thought of as an integrative process which organizes the diverse elements into an integrated unit. The structure has many categories—atoms, ions, molecules, cells, organs, organ systems; but these structures, at different levels of complexity, function together harmoniously as part of the "field". The living field is stable, yet its stability is not static but dynamic. Thus protoplasm is chemically very unstable, but an organism like a man may function in the same recognizable individual form for a century. The individual atoms and molecules are undergoing continuous change, but the pattern, the "field", remains until a limiting homeostatic mechanism breaks down and the organism dies.

The principle of homeostasis is illustrated in the text by many examples, earthy and theoretical. Indeed every chapter in this book is an illustration of this principle. It is an extremely useful one in biology; like the theory of evolution, it binds scattered facts, apparently unrelated and confusing, into a sane whole.

General comments are presented on the use of mathematics in biology, with special reference to the relative significance of rational and empirical equations.

Chapter 11

Homeothermy, Temperature in Life Processes, and Productive Efficiency

Uniformity of the internal environment is the condition for free and independent life. *Claude Bernard*

Homoiothermicity . . . was bound to arise in . . . animal life tending to free itself from the domination of the inorganic. *Joseph Needham*

11.1: Introduction. Feathers, fur, and hair, which one phase of animal husbandry cultivates, serve the animal wearer in essentially the same way as they later do the human wearer. They are aspects of *physical*¹ temperature-regulation in warm-blooded animals or *homeotherms*. Homeotherms also employ *chemical*¹ temperature-regulating mechanisms, involving metabolic changes, to keep the body temperature constant.

The larger homeotherm finds no need of an annual migration to avoid reasonably low temperature. Many small homeotherms, especially small birds, migrate seasonally because they have a relatively larger surface area in comparison to body weight than do large animals and heat loss is proportional to surface area (Chs. 13, 17). The geographic distribution of animals is thus dependent on body size, that is, on the ratio of surface area to body weight, and on other factors. Geographic distribution, efficiency, and profitableness of farm animals of different size is likewise dependent on temperature and other geographic conditions.

Cold-blooded animals, or *poikilotherms*, whose body temperature fluctuates with that of the environment, are evidently more dependent on outside temperature than homeotherms. While the rate of living of homeotherms is approximately the same throughout the year, that of poikilotherms varies with latitude and temperature (Ch. 8). When the environmental temperature falls to freezing, their body cells freeze, causing death. Small poikilotherms, therefore, descend below the frost line seasonally, to the lower depths of water, mud, or soil or, like some insects, migrate to warmer climates.

¹ Other *physical* heat-regulating mechanisms: moisture vaporization from skin (sweating) and lungs (panting); moving of blood to surface (for cooling in sweating species) or to interior; layers of fat for insulation against cold; huddling, looking for shelter, for warm sun, for cool shade, etc. *Chemical* temperature regulation: changing metabolic rate by various devices, such as shivering, changing muscle tension, increased adrenaline and thyroxine production, and so on.

Poikilotherms which cannot thus migrate often perish. Some very small poikilotherms desiccate and encapsulate for protection.

The disappearance of the great reptiles in the Cretaceous and Eocene periods is often attributed to unusual temperature changes which permitted homeotherms, but not poikilotherms, to survive. Strange as it may seem, some homeotherms (the sweating species) also stand higher temperature better than some poikilotherms.

Homeothermy has many aspects, theoretical, agricultural and engineering. The theoretical aspect is concerned with homeothermic mechanisms; the agricultural, with the influence of environmental temperature and humidity on productivities and efficiencies of farm animals; the engineering, with ventilation, heating and cooling (air conditioning). We shall discuss each of these; the theoretical and numerical discussions are presented in small type, the practical and general in large type.

Homeotherms may be divided into several classes according to body temperature,² which ranges from about 36° C (96° F) in elephants to about 43° C (109° F) in small birds. In general, the rectal temperature of mammals is about 38° C (100° F) and of birds, 4° C higher, namely, 42 to 43° C (107–109° F). It is, however, about 37° C (98.6° F) in man. Typical rectal temperatures: cattle 101° F (38.5° C), horses 100° F (38° C), sheep 103° F (39° C), goats 104° F (40° C), swine 103° F (39° C), cat and dog 101.5° F (38.6° C), rabbit 103° F (39.5° C), chickens 107.1° F (41.7° C), goose 105° F (40.8° C), dove 41.8° C, rat 37.3° C, elephant 35.9° C, marmoset 37° C.

Rectal temperature classes:

36–38° C (96–101° F): men, monkeys, mules, asses, horses, rats and mice, elephants.

38–40° C (100–103° F): cattle, sheep, goats, dogs, cats, rabbits, pigs.

40–41° C (104–106° F): turkey, goose, duck, owl, pelican, vulture, bittern.

42–43° C (107–109° F): fowl, pigeon, turkey, quail, partridge, pheasant, English sparrow, bluejay, starling, bobwhite.

The higher mammals and birds are very sensitive to temperature increase in the body; a rise of only 3° C (5.4° F) above normal for some time in the adult may be fatal. The young are less sensitive.

The body temperature of chicks rises from about 39° C (103° F) the first day, through 40° C (104° F) the second day, 41° C (106° F) the third day, exact temperature depending on time of day measured (Fig. 11.5B).

When fowl eggs are incubated at 37.8° C (100° F) their temperature begins to rise by the sixth day—reaching about 40° C (104° F) by the eighteenth day of incubation.³

Egg temperatures of wild birds under natural incubation conditions are, on the average, 34° C (93° F), being 33.6° C for passerine birds, and 36.4° C for galliforms. A

mallard nest with 18 eggs showed a difference of 12° C (22° F) between an egg in the center of the nest and one at the outer edge.⁴

Some animals are intermediate between homeotherms and poikilotherms. Thus⁵ the duckbill and Australian anteaters not only have the relatively average low body temperature of 25° C (77° F), but their body temperature changes by about 10° C with an environmental temperature change of 30° C.

11.2: Relative productivities and efficiencies of homeotherms and poikilotherms. In poikilotherms the speed of the life processes, such as feeding, growth, metabolism, aging, etc., increases with temperature up to a certain limit (depending on species) in accordance with the Van't Hoff law, just as the speed of inanimate reactions does. Since temperature probably affects the anabolic (productive) and catabolic (destructive, maintenance, aging) processes to an equal degree, the gross or overall energetic efficiency of the transformations is likely to remain unchanged. By the same reasoning, if all other conditions are equal, the gross energetic efficiency is likely to be the same in poikilotherms and homeotherms in spite of enormous body temperature and energy-metabolism differences. This is illustrated by Table 11.1

TABLE 11.1.—Time and maintenance energy expended for doubling body weight in homeotherms and poikilotherms. Data rearranged from Rubner.⁶

Doubling Body Wt.	Body Weight (gms)			Time required to double body wt. (days)			Maintenance energy expended (Metabolism) (Cals)		
	Cat	Dog	Fish (Pike)	Cat	Dog	Fish	Cat	Dog	Fish
"Birth Wt"	87	225	70						
1	174	450	140	8	10	270	3200	3000	3300
2	348	900	280	12	13	300	4000	3070	2350

which shows that both maintenance cost and growth rate are enormously higher in warm-blooded animals (cat, dog) than in cold-blooded (Pike), with the net result that efficiency is apparently the same in both.

The following data by Barthelemy and Bonnet,⁷ cited by Needham, on frog's eggs up to disappearance of external gills confirm the above conclusion based on Rubner's data.

Temperature (°C)	Development time (days)	Gross efficiency (%)
9	30	75
11	22	73
14	20	75
21	8	75

Rahn⁸ estimated that the maximal efficiency of energy utilization in growth is of the same order in the vertebrates, insects, and bacteria studied (see, however, Ch. 3).

⁸ Rahn, O., *Growth*, 4, 77 (1940).

According to Rahn's estimates, one Cal. of food produces the following Calories in body tissue: in pig, 0.2-0.4; trout, 0.18-0.31; cockroach, 0.34-0.35; mold, 0.58-0.70; colon bacilli, 0.13-0.24; pseudomonades, 0.21-0.22.

Tyler⁹ reported for eggs of some marine invertebrates, that the total oxygen consumed in reaching a given stage of development at different temperatures (7.5°, 10°, 12°, 15°, 20°, 22°, 25° C) was, with one exception, the same within the limits of error of the measurements; this occurred in spite of the fact that the speed of attaining the given stage increased rapidly with increasing temperature.

11.3: Temperature coefficients and the Van't Hoff-Arrhenius equation in life processes. A fascinating branch of biologic investigation is concerned with the search for analogies—even if they are empirical *form* analogies and gross oversimplifications—between the characteristics of given biologic processes and those of some inanimate process, such as that of an inorganic chemical reaction. Such analogies introduce order, and are often suggestive and practically useful. As part of this type of research a considerable literature has developed^{10,13} on the applicability of the Van't Hoff¹¹ and Arrhenius¹² temperature-coefficient equations, formulated from thermodynamic reasoning for simple inorganic systems, on the rate of biologic processes.

The Van't Hoff rule in linear ratio form states that (within certain limits) the speed of chemical reactions is doubled or trebled, that is, increased by 200 to 300 per cent, for an increase of 10° C or 18° F in temperature, or is increased by 20 to 30 per cent for an increase in 1° C.

The above statement may be represented by the equation

$$Q_{10} = \frac{S_2}{S_1} = 2 \text{ to } 3 \quad (11.1)$$

in which Q_{10} may be called the Van't Hoff coefficient, and S_1 and S_2 represent the speeds of the process at temperatures t° C and $(t + 10)^\circ$ C.

Thermodynamic considerations indicate that the Absolute temperature scale should be employed and that the relation should be exponential rather than linear-ratio. Arrhenius¹², therefore, suggested the equation

$$S_2 = S_1 e^{\frac{u}{T_2 T_1} (T_2 - T_1)} \quad (11.2A)$$

in which S_2 and S_1 are the speeds (Arrhenius represented them by the reaction-velocity constants, K_2 and K_1) at Absolute temperatures T_2 and T_1 ; e is the base of natural logarithms, and the value 2, of course, represents the gas con-

stant R (Ch. 2). In simple inorganic chemistry u is supposed to represent, in accordance with thermodynamic reasoning, the molecular heat of formation. In biology u is referred to as *temperature coefficient*, *thermal increment*, or *temperature characteristic*.¹³

By taking logarithms, \ln , of (11.2A), we have:

$$\ln S_2 - \ln S_1 = \frac{u}{2} \left(\frac{T_2 - T_1}{T_2 T_1} \right) \quad (11.2B)$$

indicating that the applicability of this equation to data is easily determined by plotting¹³ the logarithms of S against the reciprocals of T . Its applicability can also be tested by solving for u for several temperatures:

$$u = 2 \frac{T_2 T_1 (\ln S_2 - \ln S_1)}{T_2 - T_1} \quad (11.2C)$$

Arrhenius¹⁴ suggested that when $T_2 - T_1$ is small, $T_2 T_1$ is virtually a constant. Therefore, combining the two constants $u/2$ and $T_2 T_1$ into one constant, c , we have:

$$S_2 = S_1 e^{c(T_1 - T_2)} \quad (11.3)$$

We prefer to write it simply, as

$$S = A e^{kt} \quad (11.4A)$$

in which S is the speed of the process (as of growth, etc.) at ordinary temperature t ; A is an empirical constant (value of S when $t = 0$); and k is the differential increase in relative rate of change (as of growth) for 1°C change in temperature. It is evident¹⁵ from equations (11.2C) and (11.4) that $u = 2kT_1 T_2$.

By taking logarithms of (11.4A),

$$\ln S = \ln A + kt \quad (11.4B)$$

The applicability of equation (11.4) to data is proved by the linear distribution on arithlog paper, and the value of k is the slope of the curve (times 2.3) of S against t . The value of k is 0.07 for a Q_{10} value of 2, meaning that the differential, or instantaneous, rate of change in speed, S , is 7 per cent per 1°C change in temperature. (The reason that the change in speed is 7 per cent for Q_{10} of 2 and not 10 per cent as given by the linear equation (11.1) is explained in Chs. 16 and 17.) This (our) method is understandable, as actual data are used, and k is the relative rate, or percentage rate when multiplied by 100, of increase in speed of the process per 1°C rise in temperature.

¹³ Crozier, W. J., *J. Gen. Physiol.*, **7**, 129, 189 (1924) **10**, 53 (1926) and other papers in this journal; also *Proc. Nat. Acad. Sci.*, **10**, 461 (1924).

¹⁴ Arrhenius, S., "Quantitative laws in Biological Chemistry," London, 1915.

¹⁵ Equation (11.4) may be written $K = \frac{\ln S_2 - \ln S_1}{T_2 - T_1}$.

For practical purposes the Van't Hoff Q_{10} rule, eq. (11.1), or a slight modification, as

$$Q_{10} = 1 + \frac{S_2 - S_1}{\frac{1}{2}(S_2 + S_1)} \times \frac{10}{t_2 - t_1}$$

is as good as the Van't Hoff-Arrhenius equation (11.2) because the maximum temperature range in biology—from 0° C to 40° C—is relatively insignificant in Absolute-temperature terms; and the temperature range for homeotherms is only a few degrees. Moreover, as the centigrade-temperature zero happens to coincide with the “physiological zero”,¹⁶ it seems to be the logical one to use.

Equation (11.2) is not applicable to the entire temperature range 0 to 40° C. but only for narrow segments, depending on the species of animal or rather, perhaps, on the enzyme which happens to be the limiting factor in a given temperature range. Moreover, as the temperature rises, the enzymes begin to be injured, that is, they tend to become denatured as proteins do,¹⁷ with the net result that the accelerating effect of temperature on the speed of the limiting process may be counteracted by the inactivating effect on the limiting enzyme in the limiting process.¹⁷ The change in speed of the process may, therefore, vacillate, or perhaps remain constant, for some temperature interval, and then decline. This may be the explanation of the peculiar “breaks” in the log speed — $1/T$ functions reported by Crozier and others; hence the linearity of the functions for narrow segments only, the lengths of the segments and the position of the “break” depending on the nature of the limiting enzyme and limiting process.

The fact that the speed-temperature curve breaks up into short segments reduces the significance of the question as to whether or not the relation is linear or exponential because either one can be “fitted” equally well to a sufficiently short segment. However, the numerical value of u in the Arrhenius equation (11.2) or of Q_{10} in equation (11.1) may be significant within appropriate temperature limits.

The above comments on biologic applicability refer to poikilotherms. The Van't Hoff-Arrhenius equation is less applicable to homeothermic processes because, by definition, homeothermy is a regulation which tends to keep the temperature constant in spite of fluctuations in environmental temperature. Thus, increasing environmental temperatures does not necessarily increase metabolism and body temperature, as would be expected from the Van't Hoff law; but it may stimulate the operation of counteracting mechanisms

¹⁶ Kafka, J., “The physiological zero,” *J. Gen. Physiol.*, **3**, 659 (1921). Edwards, C. L., “The physiological zero and egg development,” *Am. J. Physiol.*, **6**, 351 (1901). For developing hens' eggs the “physiological zero”, at which development just begins is about 20° C (68° F).

¹⁷ Chick, H., and Martin, C. J., “Heat coagulation of protein,” *J. Physiol.*, **40**, 604 (1910); **43**, 1 (1911); **45**, 61 and 261 (1912). The Q_{10} for denaturation of protein is not 2 or 3, but about 15. The Q_{10} for coagulation of egg albumin is several hundred.

(increased sweating and vaporization, so as to keep the body temperature constant). However, as demonstrated in Section 11.5, the Van't Hoff rule often applies to the counteracting process, *e.g.*, to increase in respiration and

Fig. 11.1. The influence of environmental temperature on walking speeds of ants (1), feeding rate of grasshoppers (2), O_2 -consumption rate of goldfish (3), aging rate (reciprocal of mortality rate) of grasshoppers (4), growth rate of grasshoppers (5). The Q_{10} , the u values, and equations were fitted by us to data on grasshoppers (by J. R. Parker, Univ. Montana Agr. Exp. Sta. Bul. 223, 1930), ants [by H. Shapley, *Proc. Nat. Acad. Sci.*, **6**, 204 (1920)], goldfish [by R. Egg and A. Krogh, *Rev. hydrobiologie*, **6**, 48 (1914)]. The Q_{10} for growth (5) and feeding (2) is nearly the same, 2.8 and 3, while the Q_{10} for aging (4) is only 1.4, meaning that the limiting reactions of the two processes are distinct. The Q_{10} of walking ants (1) is 2.1, of O_2 consumption in goldfish 2.3.

perspiration rate with increasing environmental temperature (Figs. 11.7 to 11.10).

Fig. 11.1 illustrates the influence of environmental—and consequently body—temperature, within the given limits, on the rates of *poikilothermic*

processes. The linear distribution of the data on the arithlog grid indicates that the Van't Hoff-Arrhenius equation is applicable to the given processes. Increasing temperature by 10°C increases: the walking speed of ants 2.1 times ($Q_{10} = 2.1$), the metabolic rate of gold fish 2.3 times, the senescence rate 1.4 times and the growth and feeding rates of grasshoppers 2.8 to 3 times. (Note that the growth rate is increased twice as much as the senescence rate, a fact that may be of significance in geographic differences in population density.)

Summarizing, within rather narrow limits, the speed of biologic processes tends to increase with body temperature in the same manner as in inanimate chemical reactions. The literature and computational methods are discussed briefly.

11.4: Age changes in homeothermy. As Cannon has remarked, homeothermic mechanisms are not required by the developing mammal before birth. At birth and thereafter, however, survival becomes increasingly contingent upon the exercise of these mechanisms, and so poikilothermic embryos develop into homeothermic adults.

An important adaptation to environment is that birth or hatching under natural conditions occurs during seasons when the environmental temperature is optimal (Ch. 8), thus allowing time for development of homeothermy. Depending on environmental temperature, the body temperature in children¹⁸ stabilizes (becomes fully homeothermic) between the first and second years; in rats¹⁹ in about three weeks (Fig. 11.5), in domestic fowl and chicks,²⁰ in three to four weeks (Fig. 11.5), and so on.²¹

Since a knowledge of the influence of incubation temperature is important in agriculture, we investigated the applicability of the Van't Hoff law to the speed of growth of chick embryos at various incubation temperatures.²² The results are presented in Figs. 11.2a, 11.2b, and 11.3. Fig. 11.4, plotted from data by Romanoff²³, indicates the influence of environmental temperature on hatchability, survivorship after hatching, and crippling when incubated at low non-lethal temperatures. It is evident that early growth and development in the chick can occur only within a very narrow temperature zone.

The age curve of growth in weight of the chick embryo (Figs. 11.2 and 11.3) appears to be composed of several segments, and temperature affects each of these segments differently. The data appear to follow the Van't Hoff law in the stages of growth preceding the normal 13-day stage, when $Q_{10} = 2$ to 3. Within the limits of 37° C and 41° C, the lower the temperature the

Fig. 11.2a. Growth of the chick embryo in wet weight at three temperatures

higher the value of Q_{10} . Following the normal 16-day stage, the speed of growth is repressed by both higher and lower temperatures.

The historically interesting literature on the influence of temperature on the chick embryo has been reviewed by Needham²⁴, Romanoff and others. A few of these may be

cited. Prevost and Dumas²⁵ thought that incubation might be successful between 30° and 40° C; Daerste,²⁶ between 35° and 39° C. Pembrey and Gordon²⁷ suggested that in the earliest stages the chick embryo behaves like a cold-blooded animal; and they were also the first to observe that CO₂ production in chicks increases with environmental temperature. Recent contributions are those of Romanoff,²⁸ Barott,²⁹ Byerly,³⁰ and others.

Age changes in homeothermy during aging are discussed in Chapter 18.

11.5: Homeothermic mechanisms. The temperature of the living body, like that of an inanimate object, tends to come into heat equilibrium with the environmental temperature by conduction, convection, and radiation.

Fig. 11.4. Hatchability of chicken and turkey eggs at different temperatures. The optimum temperature is between 36.5 and 37.5° C, or about 97–100° F. Low temperature induces crippling.

Definitions: Heat *conduction* is a molecular-contact process. Metals *conduct* heat readily; wool, feathers, hair, fat, silk, wood, and air conduct heat poorly. Hence, we use a metal tea pot but wooden handle, and a “warm” woolen carpet (full of air pockets) on a “cold” metal or concrete floor. The rate of heat conduction is proportional to surface area and to temperature gradient.

Heat *convection* is by air movement, as by fanning.

Heat *radiation* is by electromagnetic waves at the rate of 186,000 miles per second, in straight lines, without physical contact of bodies. The electromagnetic spectrum

includes waves ranging in length from cosmic rays, only 0.000,000,000,002 inch (or 0.000,000,01 micron), up through gamma rays, X-rays, (0.001 micron), ultraviolet rays (0.1 micron), visible light rays (V, B, G, Y, R), heat waves, Hertzian waves (.01 inch to 120 feet or 10,000 meters), radio waves (120 to 1220 feet), wireless telegraphy waves (1200 feet to 15 miles), and so on to hundreds of miles. Heat waves from the body are infrared waves, including only 5 to 20 μ (a μ is a micron, or a millionth of a meter, or a thousandth of a millimeter) in length ("Planck's law"). Heat loss by radiation depends, among other factors, on a surface quality called *emissivity*. Highly polished metals like copper or aluminum foil have a low emissivity of about 5 per cent as contrasted to 100 per cent emissivity of dead black material, 93 per cent emissivity of building materials (wood, paper, brick), 97 per cent emissivity of skin (white or "colored"). This means that if the temperature of the radiating body is higher than of the skin, the skin absorbs 97 per cent and reflects 3 per cent of radiated heat; the reverse occurs if the skin temperature is above that of the absorbing environment, absorption and emission being equal.

Several "laws" of radiation have been formulated, indicating that radiation is proportional to: temperature difference, surface area, and emissivity (Newton); surface area, emissivity, difference between the fourth powers of the absolute temperatures of the radiating body and the absorbing body (Stefan-Boltzmann); profile of projected area³¹ (Lambert). Hardy³² perfected methods for measuring heat radiation from the body.

It should be remembered in the following discussion that since the homeotherm must maintain its body temperature constant, its heat loss, or *thermolysis*, must equal its heat production, or *thermogenesis*. When the environment is hot, the problem is how to dissipate the body heat; when the environment is cold the problem is how to conserve the body heat and how to produce enough extra heat to keep the body temperature constant despite the unavoidable heat losses.

The loss or gain of heat by radiation, conduction, and convection is not a unique characteristic of living bodies, although it is only the living body that moves the blood to or from the surface for the best utilization of these mechanisms. The unique features of homeotherms are (1) conservation of body heat—reducing thermolysis—in cold weather by such means as developing fur, feathers, or subcutaneous fat, huddling as well as bundling ("social-temperature regulation") in some species, finding shelter, increasing heat production by muscular exercise or by increased production of thyroxine and/or adrenaline, reducing heat conductivity of skin by removing the blood from the surface, and reducing vaporization by decreasing respiration rate and by shutting off moisture production by the skin; (2) dissipation of body heat—increasing thermolysis—in hot weather by reversing the above processes, by reducing the skin covering, moving the blood to the surface for cooling, increasing vaporization rate by producing more surface moisture, sweat, by increasing the respiration rate, and by exposure to moving air (fanning).

Fig. 11.5a. Age curves of development of homeothermy (curve 2), body weight (curve 1), and heat production (curve 3) in rats, with respect to an environmental temperature of approximately 15° C (59° F). Unpublished chart by E. B. Brody.

Fig. 11.5b. Age curves of body temperature in chicks brooded at 28° C and 35° C. The curves for the two temperatures tend to come together with increasing age, an index of homeothermic stabilization. From J. C. Scholes and F. B. Hutt, "Relation between body temperature and resistance to pullorum," Cornell Univ. Agr. Exp. Sta. Memoir 244, 1942.

Let us first inspect Figs. 11.6 to 11.9 indicating the influence of environmental temperature on heat dissipation by moisture vaporization.

Fig. 11.6. Influence of environmental temperature on the percentages of heat loss by vaporization, convection, and radiation. Heat loss shifts from radiation to vaporization with rise in temperature.

Fig. 11.7. Influence of environmental temperature on the ratio of heat dissipation by vaporization to the total heat production (or to the total heat dissipation) plotted on arithmetic paper. Note the break in the curves at about 85° F or 28° C.

It is obvious that if the environmental temperature is the same as that of the body, the body cannot lose heat by radiation, conduction, or convection; it must lose it all by vaporization. If the environmental temperature is higher

than that of the body, the body absorbs heat from the environment—radiation, conduction, and convection are reversible processes—and the body must dissipate not only the heat *produced* by it but also that *absorbed* by it from the environment. This loss can be achieved by only one method, vaporization of moisture. Vaporization is a good cooling method because approximately 600 Calories or 2400 Btu of heat are dissipated for each quart, or liter, of moisture vaporization, and it is not unusual for a hard-working normal

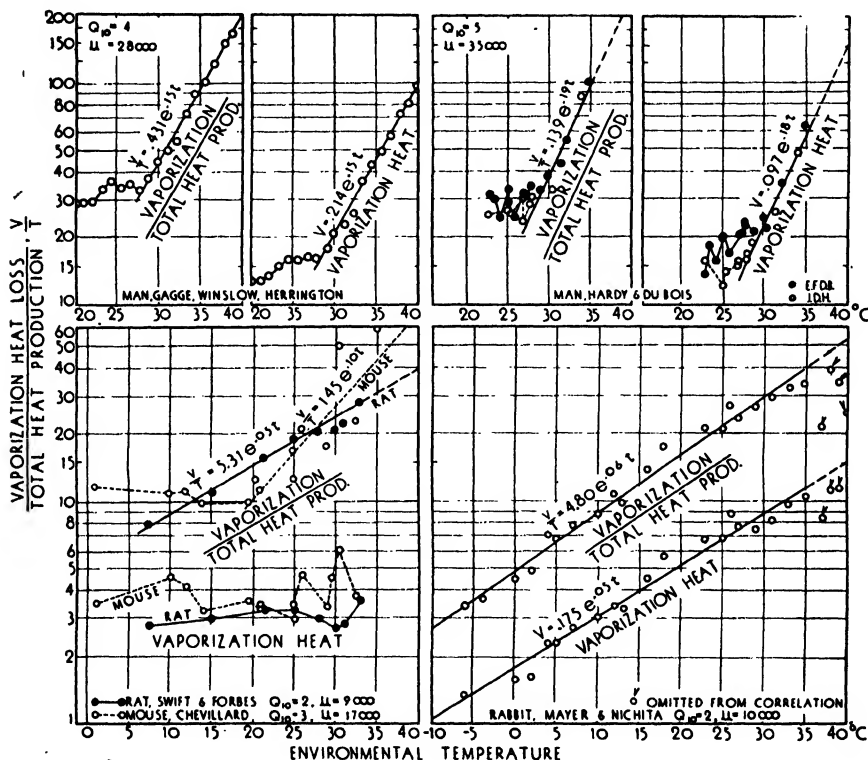

Fig. 11.8. Influence of environmental temperature on the ratio of heat dissipation by vaporization to the total heat production (or to the total heat dissipation) plotted on arithlog paper (the same data as in Fig. 11.7). Note the break in the curves at about 85° F or 28° C.

person to lose by vaporization in a hot, dry climate³³ three quarts per hour—over ten times the basal heat production or four times the heat production during hard physical labor.

The importance of vaporization is brought into dramatic relief by considering the plight of unfortunate persons lacking sweat glands³⁴. They are

³³ Adolph, E. F., and Dill, D. B., "Water metabolism in the desert," *Am. J. Physiol.*, **123**, 369 and 486 (1938).

³⁴ Sunderman, F. W., *Arch. Int. Med.*, **67**, 709 (1941).

obliged to keep their underwear moist to enable them to bear normal summer temperature and they are unable to work because of rapidly rising body temperature on slight exertion.

Fig. 11.6 shows that as the environmental temperature approaches body temperature, heat dissipation is shifted from radiation, conduction, and convection to vaporization. There is, however, a striking difference in this re-

Fig. 11.9. Influence of environmental temperature on the ratio of heat dissipation by vaporization to the total heat production (or to the total heat dissipation) plotted on arithlog paper (the same data as in Fig. 11.7). Note the break in the curves at about 85° F or 28° C.

spect between the profusely sweating species, man, and the other species represented in Figs. 11.7 to 11.9 which are slightly or non-sweating.

Figs. 11.7 to 11.9 show that there is a sharp break in the curve for man at temperature 29° C or 84° F (the "critical temperature" for sweating³⁵ in man is between 27° and 32° C). Up to this temperature vaporization increases irregularly, up to 35 per cent of the total heat dissipation; following this temperature, there is a very steep but orderly rise, a linear rise on the arithlog

³⁵ Kuno, Y., "The physiology of human respiration," London, 1934.

grid charts (Figs. 11.8 and 11.9), at the differential rate of 15 to 19 per cent per 10°C rise in environmental temperature, the Q_{10} being 4.5 to 4.9, or the u , 28,000 to 35,000. Thirty-five per cent of the heat production is dissipated by vaporization at 29°C (84°F), 100 per cent at 35° – 36°C (95° – 99°F), and 200 per cent at 40°C (104°F). In other words, at about 100°F all the thermolysis in man is by vaporization; and at 104°F the body absorbs as much heat from the environment as it produces, so that thermolysis by vaporization is twice the thermogenesis. When the inhaled temperature is 43°C (109°F), the exhaled air is 34°C (93°F): the air is cooled³³ by some 16°F in passing through the body.

The above discussion is for man, a profusely sweating species. The same holds true for the burro³³ (donkey or ass), which is also profusely sweating, and perhaps for the horse and mule.

The curve of heat dissipation with increasing environmental temperature is quite different in the slightly sweating or perhaps non-sweating species, which includes the other farm and laboratory animals: cattle, sheep, swine, rabbits, rats and mice, cats and dogs³⁶. Figs. 11.7 to 11.9 show no break for these species at 29° or indeed at any other temperature. Their respiration rate goes up enormously, but this does not help the animal much above 35°C (95°F). The increase in percentage dissipation by vaporization rises slowly, about 10 per cent per 1°C rise in environmental temperature for mice and 5 to 6 per cent for the other species: the Q_{10} is 3.2 for mice and 1.7 for the other species; the u is 17,000 for mice and 10,000 for the other species. This plight of non-sweating species in hot weather is evidenced by the fact that under such conditions man dissipates only one-third of his heat by vaporization from the respiratory passages, two-thirds from the skin.

The respiration rate in man is relatively independent of temperature. There is some tendency toward a *lower* respiration rate in summer than in winter, but this is attributed³⁷ to seasonal differences in sunlight rather than temperature.

In cattle³⁸, on the other hand, as shown in Fig. 11.10—and this is true of

doubled for an increase of 10° C (18° F) in the environmental temperature. According to the Van't Hoff law, the speed of a process is doubled for an increase in 10° C in the reacting system; but for the respiration rate it is doubled not for an increase in 10° C in the body, which is the reacting system, but in the environment. How shall one who accepts the Van't Hoff law explain this peculiar type of applicability? It may be that the temperature of the thermostatic trigger mechanism varies directly with the environmental temperature, even though the temperature of the body as a whole is not changed. The same explanation may be given for the increase in sweating rate in man (Figs. 11.7 to 11.9).

Fig. 11.10 also contrasts the effect of rising environmental temperature on the pulse rate of sweating and non-sweating species^{38, 40}. In sweating species, the blood is shunted to the surface where it is cooled by the vaporization of sweat. The internal blood deficiency resulting therefrom is compensated by increased pulse rate. In non-sweating species, on the contrary, the pulse rate declines with increasing environmental temperature, presumably because in the absence of sweat the skin is not cooled. The blood may, therefore, be sent to the interior instead of to the surface, as in the case of sweating animals, and the overabundance of blood in the interior with its associated O₂ reservoir may depress the pulse rate.

The contrasting influence of a given high environmental temperature on the skin temperatures of sweating and non-sweating animals may be inferred from the relative dry- and wet-bulb thermometer readings. In Boulder City, Nevada, where a dry-bulb thermometer registered³³ 40° C and a wet-bulb thermometer read 22° C, the skin of a non-sweating animal probably "felt"⁴¹ a temperature near 40° C (104° F) while that of a sweating animal "felt" a temperature nearer 22° C (72° F).

In cold weather the problem is, of course, to reduce heat loss by such devices as reducing vaporization (by cutting off sweating), reducing respiration rate, shunting the blood from the surface to the interior, huddling, and in the long swing, producing warm coverings of fur or feather and subcutaneous fat. The so-called chemical method of heat regulation consists of increasing thermogenesis by exercise, including shivering and muscle tension⁴², increasing *SDA*

⁴⁰ Hardy, J. D., and DuBois, E. F., "Basal metabolism, radiation, convection, and vaporization at temperatures 22° to 35° C in man", *J. Nut.*, **15**, 481 (1938).

⁴¹ The wet-bulb thermometer is an ordinary mercurial thermometer with the bulb tightly enclosed in a cloth, the lower end of the cloth extends beyond the bulb and deep into water. The vaporization from the wet cloth cools the wet bulb with resulting lower temperature. The *effective temperature* of the air-conditioning engineer is, indeed, estimated by comparing the temperature readings on the wet and dry-bulb thermometers.

⁴² Swift, R. W., "Influence of shivering on heat production," *J. Nut.*, **5**, 227 (1932). (Shivering increases heat production 400%; it begins when skin temperature attains 19° C (66° F).)

by greater food intake (Ch. 4), and increasing adrenal and thyroid activity, adrenaline and thyroxine being powerful metabolic accelerators.

Fig. 11.11a. Diagram of the influence of environmental temperature on heat production and body temperature.

Fig. 11.11a. Illustrates Fig. 11.11 on a gopher or ground squirrel (a hibernating animal).

The relation between chemical and physical heat regulation is illustrated in Fig. 11.11, in which heat production is plotted against environmental tem-

perature, modeled somewhat after Giaja⁴³. Temperature segment *B-B'* includes the zone of thermoneutrality and also that of physical temperature regulation. At *thermoneutrality*⁴⁴, indicated by *A* in Fig. 11.11, the animal does not employ thermoregulatory devices: the environmental temperature is perfectly adjusted to keep the body temperature normal without regulation, and the animal feels neither hot nor cold. Thermoneutrality is presumably in the air-conditioning engineer's "comfort zone". The comfort zone for man is considered to be between 22° and 30° C or 72° to 85° F.

Thermogenesis begins to increase at environmental temperature *B'* in order to balance the increasing thermolysis. At environmental temperature *C* the body temperature begins to decline despite the increasing thermogenesis. The temperature-regulating mechanism is no longer able to cope with the cold.

Environmental temperature *D* in Fig. 11.11 represents the position at which heat production is maximum, the *summit metabolism* of Giaja⁴³. Further decline in environmental temperature breaks down the homeothermic mechanism, and heat production as well as body temperature declines.

The following table, compiled from Giaja's papers, illustrates the levels of summit metabolism, metabolic quotient, and thermogenic reserve. These values vary with

Animal	Body weight (g)	Cal/sq meter		Metabolic quotient (summit/basal metabolism)	Lowest temperature, at which animal can maintain normal body temperature for 1 hr.	
		Basal metabolism	Summit metabolism		°C	°F
Swallow	19	1630	4830	3.0		
Mouse	18	1246	4350	3.4		
Dog	6375	1000	3500	3.5

⁴³ Giaja, J., "La marge de thermogénèse et le quotient métabolique au cours du développement embryonnaire et de la croissance," *Ann. physiol. physico-chimie biol.*, 1, 596 (1925). "Homéothermie et thermorégulation," "Actualités scientifiques et industrielles," Nos. 576 and 577, Paris, (Herman et Cie, 6 rue de la Sorbonne), 1938. "Le métabolisme de sommet", *Réunion plénière Société de biologie tenue less 17 et 18 mai* (1929).

⁴⁴ Thermal neutrality, or thermal zero, is the environmental temperature at which heat loss from the body is equal to the *minimum* heat production. This thermoneutrality temperature is 7° to 10° C (12° to 18° F) below the rectal temperature and in man about 5° C (9° F) below the *average* skin temperature, although the temperature of the feet is nearly the same as of the environment at thermoneutrality.

species and size of the animal and with the temperature to which the animal is acclimatized⁴⁶. Thus in rats the metabolic quotient⁴⁶ is 1.3 when it is acclimatized to 31° C, 2.8 to 18° C, 3.4 to 1° C.

The above table shows that the *thermogenic reserve*, or the thermal adaptability, is 2 to 3 times as great in the eagle as in the swallow. Immature animals have a smaller reserve than mature ones, and Giaja employed this metabolic reserve as an index of development of the heat-regulating mechanism in early growth. The homeothermic accommodation *range* (from temperatures *B* and *D* in Fig. 11.11) is 130° to 140° C in ducks and geese, 125° C in pigeons, 85° C in rabbits, 80° C in doves and larks, 70° to 90° C in fowl, 70° C in passerine birds (finches, sparrows, etc.) 65° C in rats, 55° C in guinea pigs.

On the right, high-temperature, end of the curve in Fig. 11.11, the body temperature begins to rise at environmental temperature *B*. The position of *B* varies with (1) sweating mechanism; (2) relative humidity and air motion; (3) nature of insulation (fur, feather, fat); (4) ratio of surface area to weight (a function of size, the larger the

Fig. 11.12. The influence of acclimatization to a 30°-32° C environment on the metabolism of a rat previously housed in a 16°-20° C environment.

animal the smaller the surface per unit weight); (5) body temperature; (6) other factors, such as acclimatization. Figs. 11.11a and 11.12 illustrate the influence of acclimatization on gopher and rat respectively.⁴⁷ In the rat⁴⁸ the body temperature begins to rise at 32° C if acclimatized to -12° C, at 33° C if acclimatized to 12°-18° C, at 35° C if acclimatized to 29°-32° C.

Herrington⁴⁹ reported that temperatures *B* and *B'*, the temperature limits of thermo-neutrality, are 27-29° C (81-84° F) for rats, 28-30° C (82-87° F) for mice, 29-31° C (84-

⁵⁰ Herrington, L. P., in the book "Temperature", etc., Am. Inst. Physics, Reinhold Pub. Corp., 1941.

88° F) for guinea pigs. However, Swift and Forbes⁵⁰ reported 30–33° C (86–91° F) for rats. The difference between Herrington and Swift's values for rats may be explained by differences in: speed of ventilation, humidity, and acclimatization. The temperature of thermoneutrality for women (nude) was reported to be⁵¹ about 30° C (86° F). There are scattered references in the literature⁵² on temperatures of thermoneutrality (with reference to heat production) of other species: 15–20° C (59–68° F) rabbit, 21–25° C (69–77° F) sheep, 13–21° C (55–70° F) goat, 20–26° C (68–78° F) dog, 20–29° C (68–84° F) chimpanzee, 18–25° C (65–77° F) goose, 20–28° C (68–82° F) turkey, 16–28° C (62–82° F) fowl, 24–25° C (75–77° F) pigeon, 31–36° C (87–96° F) dove, 34–36° C (93–97° F) canary, 30–31° C (86–88° F) finch. Lee⁵³ reported that thermoneutrality for the rabbit is 28° to 29° C (82–84° F).

It is instructive to note that the comfort zone of some poikilotherms on the farm is about the same as that of homeotherms. Thus, "Grasshoppers are forced to climb vegetation to escape heat which is at air temperature of about 80° F (27° C) and soil temperature of approximately 107° to 113° F (42° to 45° C)". "Maximum feeding is interrupted when air temperatures go much over 80° F, or soil temperatures above 113° F; the grasshoppers then climb vegetation, where most of them remain motionless only now and then nibbling on the vegetation on which they are resting."⁵⁴

However, preceding this optimum temperature, the influence of environmental temperature on all metabolic processes of poikilotherms, including heat production, is directly opposite to its influence on homeotherms (Fig. 11.1). This temperature effect on insects is obviously very important, because it indicates that prior to the comfort zone the agricultural destructiveness of insects is increased 2 to 3 times for an increase of 10° C (or 18° F) in the environmental temperature.

Figs. 11.13 and 11.14 illustrate factually parts of the diagram in Fig. 11.11 and emphasize the following features: (1) other conditions being equal, the larger the animal, the flatter⁵⁵ its heat-production curve with decreasing environmental temperature; (2) if an animal is acclimatized to a low environmental temperature it produces more heat at higher temperatures than if it is acclimatized to the higher temperature (it takes time to change the thermostatic controls from one to another temperature level⁵⁶); (3) the environmental-temperature range which animals can withstand on the cold side of thermoneutrality is very much greater than on the hot side.

Little is known about some of the homeothermic mechanisms, how, for example, fur or wool develops on approaching cold weather⁵⁷; how more

surface temperature⁶⁰. It is now generally known that the sympathetic nervous system controls the caliber of many blood vessels and therefore, the conducting or insulating properties of the skin.

The nervous heat-regulating center is in the hypothalamus⁶¹, at the head of the spinal cord, just below the cerebrum. In addition to the vasomotor con-

⁶⁰ Bernard, C., *Compt. Rend. Soc. Biol.*, 4, 168 (1852).

⁶¹ For review of his own important work and the literature, see Ranson, S. W., *Proc. Assn. Res. Nerv. and Ment. Dis.*, 20, 342 (1940). See also Rogers, F. T., *Am. J. Physiol.*, 49, 271 (1919); 66, 453 (1923), and other papers.

trol of the caliber of the blood vessels and therefore flow and distribution of blood, the nervous system also controls the arrangement and position of hair or feathers—as in “ruffling” of feathers or “raising” of hair—so as to decrease or increase thermolysis. Incidentally, “goose flesh” in man is an obviously residual or surviving skin mechanism for arranging the fur which he lost. Tensing of muscles or shivering and other muscular activities associated with increasing heat production are under nervous control, directly or indirectly.

As an example of a possible indirect nervous control one thinks of the anterior pituitary which receives innervation from the hypothalamus, the heat-regulating center. Under hypothalamic influence, approaching cold may stimulate the pituitary to produce more thyrotropic⁶² and adrenotropic hormones which stimulate thyroids and adrenals to produce more thyroxine (for slow, seasonal, temperature changes) and adrenaline⁶³ (for rapid temperature changes)⁶⁴.

Keeping rats in a cold environment for some time raises their basal metabolism even if measured at thermoneutrality (Figs. 11.12 to 11.15). This increase in heat production is attributed⁶⁵ to increased thyroid activity by cold. However, Lee and Lee⁶⁶ reported that the thyroid is not necessary for maintaining normal body temperature at low temperatures. Chahovitch⁶⁷ reported that thyroidectomy in the rat lowered “summit metabolism” from 17.6 to 9.3 Cal/kg/hr.

Chevillard, Hamon and Mayer⁶⁸ reported an increase in weight of the liver in mice kept in the cold. They⁶⁹ also reported the involvement of adrenal hormones and choline in heat regulation. Castration⁷⁰ appears to reduce the level of summit metabolism.

Bazett⁷¹ reported that the blood volume of healthy men in Philadelphia is 15 to 40 per cent higher in summer than in winter; men exposed for a few days to high temperatures in midwinter experience an increase in blood volume, although not so striking as

in summer. Cardiovascular changes were also observed.⁷² The increase in blood volume must be related to the increase in the peripheral vascular bed. Bazett believes that the pituitary may be concerned in the changes of urine output occurring in the adaptation period.

Fig. 11.15. A comparison of the influence of environmental temperature on metabolism, and on the temperature of several body regions, heat loss, and skin conductivity for heat. Modified from Hardy and Du Bois (see text).

11.6: Applications. The facts and principles of homeothermy may be utilized in calorimetry, animal husbandry, air-conditioning engineering, and medicine.

11.6.1: Insensible-perspiration calorimetry. In 1614 Sanctorious wrote a book in which he gave much attention to “perspiratio insensibilis”, and decorated it with an engraving of a man suspended from a steel-yard scale watching himself losing weight—a rather fascinating pastime. This weight loss does not include liquids or solids, which are “sensible”; it includes only “insensible” losses, *e.g.*, water vapor and carbon dioxide. However, when the R.Q. is

⁷² Bazett, Scott, and Sunderman, *Am. J. Physiol.*, **123**, 11 (1938).

0.727, the CO_2 weight exhaled just balances the O_2 weight consumed⁷³ so that all "insensible" loss is vaporized moisture alone. The heat dissipated is computed by multiplying the weight of water vaporized by the latent heat of vaporization of the water (0.58, in the body nearer 0.60 Cal/gm water). Benedict and Root and others suggested that the heat production may be determined from insensible perspiration, since the heat dissipated by vaporization is an approximately constant percentage of the total heat produced or dissipated under a *given set of conditions* (Figs. 11.7–11.9), that is, below the sweating temperature of about 27° C (in man).

From Figs. 11.7 and 11.8 it is evident that this method is not applicable with precision following temperatures of 27° or 30° C, and that even prior to this temperature the percentage heat loss by vaporization is very sensitive to environmental temperature and other conditions. It increases from about 18 per cent of the total heat dissipation at 18°C (65° F) to about 35 per cent at 30° C (85° F), then very steeply to 100 per cent at 36° C (97° F), and so on.

As previously noted, in man (sweating species), about $\frac{2}{3}$ of the insensible moisture loss is from the skin, and $\frac{1}{3}$ from the respiratory passage⁷⁴. In non-sweating animals, the moisture loss from the skin is less, only that which reaches the surface by "osmosis" or "physical permeability" rather than by glandular (sweating) activity. It has not been determined how environmental temperature affects the ratio of "osmotic" moisture⁷⁵ to sweat-moisture vaporization in sweating and (relatively) non-sweating species.

Incidentally, it should be possible to compute from the ventilation rate, that is, from the volume of air exhaled per unit time, the moisture vaporized from the respiratory passages, since the exhaled air is practically saturated with

⁷³ The molar weight of O_2 is 0.727 of the molar weight of CO_2 : $\frac{\text{O}_2}{\text{CO}_2} = \frac{32}{44} = 0.727$;

hence, when the R.Q. is 0.727 the CO_2 exhaled just balances the O_2 absorbed. When the R.Q. is less than 0.727, more O_2 is absorbed than CO_2 exhaled, and the insensible water loss is greater than the total insensible loss; when the R.Q. is greater than 0.727 more CO_2 is given off than O_2 is taken in and the insensible water loss is less than the total insensible loss. The production of methane would, of course, complicate the situation. The insensible perspiration, I. P., may, therefore, be defined symbolically by the equation

$$\text{I.P.} = \text{H}_2\text{O} + (\text{CO}_2 - \text{O}_2)$$

or the moisture (H_2O) vaporized, by the equation

$$\text{H}_2\text{O} = \text{I.P.} - (\text{CO}_2 - \text{O}_2)$$

in which CO_2 and O_2 represent the weights of CO_2 produced and O_2 consumed. The value of $(\text{CO}_2 - \text{O}_2)$ is slight in any case, and zero when the R.Q. is 0.727.

⁷⁴ Richardson, H. B., "The effect of the absence of sweat glands on the elimination of water from the skin and lungs," *J. Biol. Chem.*, **67**, 397 (1926). F. C. Houghten, *Am. J. Physiol.*, **88**, 386 (1929), estimates that at 70° F (21° C) 25% of the heat is lost by vaporization: 16 per cent by vaporization from the skin and 9 per cent from the lungs; 50 per cent by radiation and 25 per cent by convection.

⁷⁵ Hancock, W., and Haldane, J. J., "The osmotic passage of water and gases through the human skin," *Proc. Roy. Soc.* **111B**, 412 (1932). Hancock, W., *et al.*, "The loss of water and salt through the skin", *Id.*, **105B**, 43 (1930). For influence of temperature on insensible perspiration in man, see also Kuno³³; Adolph, E. F., *Am. moisture at an almost constant temperature. Thus, assuming that the temperature of expired air in cattle is 38° C, and that it has a water vapor pressure of 49.8 mm Hg, the expired air contains $49.8/760 \times 100 = 6.6$ per cent water.

As noted, Benedict and Root⁷⁶ suggested using the insensible perspiration method for estimating heat production. Newburgh⁷⁷ perfected the method for long periods of observation on man, and Levine⁷⁸ and associates on infants.

In regard to farm animals, Lefèvre and Auguet⁷⁹ reported that the heat loss by vaporization in sheep increases with increasing environmental temperature.

Mitchell and Hamilton⁸⁰ reported that in steers the heat loss by vaporization ranged from about 15 per cent of the total heat loss at 43° F, to about 42 per cent at 69° F, (Fig. 11.7) and that following shearing the insensible loss decreased by from 5 to 30 per cent (average 20 per cent). The insensible loss was also influenced directly by the amount of water consumed (the skin is a water-storage organ, Ch. 10) and inversely by dehydration, and also by the individuality of the animal.

In connection with the influence of shearing on heat loss by vaporization, it is instructive to note that, although under given conditions normally feathered fowl lost 49 per cent of their heat by vaporization, scantily-feathered frizzle fowl lost only 17 per cent of their heat by vaporization⁸¹ (because the normally-feathered bird loses little by radiation).

Mitchell and Hamilton's results substantiate those of Benedict and Ritzman⁸², Kriss⁸³, Mayer, Lefèvre, Kayser⁸⁴, and others, namely, that heat dissipation as latent heat of vaporization varies with temperature and other factors (Fig. 11.7). Consequently, with the exception of very special conditions, insensible perspiration calorimetry is not the best method of measuring heat production or energy metabolism.

11.6.2: Partitional calorimetry. The evaluation of heat dissipation from insensible perspiration alone is somewhat crude. The heat produced by the

body may be evaluated more precisely from four measurements: (1) vaporization, (2) infrared (heat) radiation, (3) conduction and convection, and (4) change of heat storage in the body. Winslow and associates⁸⁶ are attempting to develop a method, which they call *partition calorimetry*, and which they claim to be superior to the conventional direct or indirect calorimetry because (1) it indicates the manner in which the heat is lost; (2) it has no time lag to mask transitory and adaptive phenomena; (3) by proper adjustment of temperature and of radiating walls of the enclosure, radiation, convection, and vaporization may be varied independently and their interrelations investigated.

Partition calorimetry involves correction for changes in body temperature. Burton⁸⁸ estimates the average body temperature by the following relation:

$$\text{Average body temperature} = 0.65 \times \text{rectal temp.} + 0.35 \text{ average surface temperature}$$

Incidentally, there is a temperature gradient⁸⁷ of 4° to 5° C between the body interior and the body surface, and Burton⁸⁸ estimates the conductance of heat from the interior to the surface by the relation:

$$\text{Conductance} = \frac{\text{rate heat loss from surface}}{\text{surface area} \times (\text{rectal less skin temperature})}$$

The so-called body temperature is a "spot temperature" and various parts of the body, especially different regions of the skin, vary enormously in temperature,⁸⁹ as illustrated in Fig. 11.15. When the room temperature is about 22° C, the rectal temperature in man is about 37° C, abdomen 35°–36° C, feet 27° C, and so on. The rectal temperature is least sensitive to changes in environmental temperature, the toes most sensitive, and so on.

The rate of heat loss from the nude body depends primarily on the peripheral circulation, but is modified by the amount of subcutaneous fat (the insulating value of fat is 3 times that of water). The greatest vasomotor changes are in the extremities, especially in the fingers and toes (less in hands, still less in forearms);⁹⁰ hence the hands and feet are among the most effective temperature regulators (heat radiators). About 30 per cent of the total vaporization comes from the hands and feet, although their surface area is only 12 per cent of the total body surface.⁹¹ The ability to withstand rapid changes in environmental temperature depends on the rapidity of response of blood flow from or to the body interior, and especially to the extremities.

Incidentally, emotional breaking into "cold sweat" and "cold hands", especially cold fingertips, often associated with blushing, indicates suggestive interrelations in the central nervous system, the brain.⁹²

11.6.3: Effect of cold weather on productivity and efficiency. It is generally known that farm livestock are wintered without apparent injury on the open range in severe winter weather. For instance, the winter temperature at Miles City, Montana, is frequently -40°F (-40°C) yet horses, cattle, and sheep in the government experiment station there are wintered outdoors without injury. In 1907 Waters,⁹³ at the Missouri Station, reported that beef cattle did better wintered outdoors than when conventionally housed. Dice⁹⁴ reported that dairy cattle wintered outdoors (9° to 27°F or -13° to -3°C) produced as well as when conventionally housed, and the feed cost of maintenance was not increased by the lower outdoor temperature.

Jordan⁹⁵ reported that dairy cows produced from 55 to 85 per cent more heat than was needed for maintenance of body temperature, and Armsby,⁹⁶ therefore, saw no reason why a cow "might not be subjected to comparatively low temperatures without causing any increased katabolism for the sake of heat production solely".

These results are not surprising because animals wintering outdoors respond to approaching cold weather by developing highly insulating coats of fur,⁹⁷ feathers, and subcutaneous fat. By driving the blood from the surface on declining temperature, the blood is kept from cooling and the skin becomes highly non-conductive to heat (Fig. 11.15). Moreover, incidental to their productive or even maintenance processes, farm animals consume large quantities of feed associated with high heat production (Ch. 4), thus keeping the animal warm in cold weather, and making it unnecessary for the body to increase the oxidation of its tissues for maintaining normal body temperature. The rapid rise in *basal* (that is, fasting and resting) metabolism with declining environmental temperature is no indication that there is a similar rise in normally fed animals under farm conditions.

It is true that under basal-metabolism conditions the "critical" temperature (Figs. 11.11, 11.13, 11.14) of farm animals is 60° to 70°F (15 to 21°C). Such values were reported for domestic fowl⁹⁸, pigs⁹⁹, and steers¹⁰⁰.

Interesting as these "critical" values may be theoretically and for research purposes, they are probably without significance for normal farm animals under normal management conditions systems. There is need, as a basis for designing farm structures and air-conditioning, for mapping the temperature curve of heat and moisture dissipation under normal farm conditions.

At present we can employ only general considerations, which indicate that in most of this country elaborate barns are not needed for cattle, sheep, or horses—merely open sheds for protection against snow, rain, and wind.

11.6.4: Effect of hot weather on productivity and efficiency. As previously noted, sweating animals can withstand much higher temperatures than non-sweating. In non-sweating animals, at any rate in cattle, the body temperature is already above normal at environmental temperature [80°F (27°C)]

Fig. 11.16. Relation between rectal temperature and heat production in man plotted by us from data by McConnell.

(Figs. 11.10 and 11.17). Rise in body temperature is associated with a rapid rise in heat production or maintenance cost (Fig. 11.16, increasing rectal temperature by 4°F or 2.2°C doubled the heat production), and decline in productivity, as shown in Fig. 11.17, plotted from Regan¹⁰¹. When the environmental temperature was increased from 60° to 95°F (from 16° to 35°C), the rectal temperature of the cow increased from the normal 101°F level to approximately 104°F (from 38° to 40°C); the daily milk yield declined from 27 to 17 lbs.; the casein declined from 2.1 to 1.8 per cent; and the solid-not-fat declined from 8.1 to 7.6 per cent. The seriousness of the damage of high environmental temperature to milk production is evident from the fact that temperatures of 80° to 100°F are quite common in our richest agricultural regions, especially in the corn belt, where the temperature often rises to 110°F (43°C). Fig. 11.18 represents the depressing

¹⁰¹ Regan, W. M., Richardson, G. A., *J. Dairy Sci.*, **21**, 73 (1938).

influence of high environmental temperatures on feed consumption and feed utilization¹⁰².

High temperature also depresses growth. Fig. 11.19 shows¹⁰³ the precipitate decline in growth of chickens during a hot July in Columbia, Missouri,

Fig. 11.17. Influence of environmental temperature on rectal temperature and on milk production in Jersey cattle.

Fig. 11.18. Influence of environmental temperature on feed consumption, heat production, and feed utilization in dairy cattle. (From Kleiber.)

when the maximum daily temperature rose to 110° F (43° C) and the mean daily temperature to 98° F (37° C).

Fig. 11.20 shows the influence of environmental temperature on growth of

¹⁰² Fig. 11.18 was generously furnished for this book by Dr. M. Kleiber who said that this chart was originally exhibited by M. Kleiber, G. A. Richardson, and W. M. Regan at the 1934 (Ithaca, N. Y.) meeting of the Am. Dairy Sci. Assn.

chicks one to two weeks of age¹⁰⁴. This growth rate is maximum at the surprisingly low temperature of 70° F (21° C).

The water-loss-temperature diagram for the domestic fowl¹⁰⁵ indicates that in the fowl thermoneutrality is close to 75° F (24° C) and that the body

Fig. 11.19. Influence of environmental temperature on growth of chickens.

Fig. 11.20. Influence of environmental temperature on growth of chicks in a constant-temperature cabinet.

temperature must rise following 85° F (30° C) and certainly above 90° F (32° C).

Cattle native to hot countries endure hot environments better than those native to temperate countries, and this may be true of other species. Thus

Zebu, or Brahman cattle, *Bos Indicus*, stand heat better than the European cattle, *Bos Taurus*¹⁰⁶, probably because the Indian cattle have more sweat glands than European cattle, just as human natives of hot climates probably have more sweat glands per unit skin area than natives of cold climates.

There is considerable literature on the influence of temperature on reproductive behavior.¹⁰⁷ The reproducing ability declines with rising temperature above 80° F.

Warren and associates discussed the influence of temperature on egg-shell thickness¹⁰⁸, egg size¹⁰⁹, blood calcium¹¹⁰, and growth of the hen's ovum¹¹¹. Shell thickness, blood calcium, and egg size decreases with rising environmental temperature above 70° F, and the birds consumed 26 per cent less feed on raising the temperature from 60° to 95° F.

It is customary to correlate milk production and milk composition with season (see Fig. 8.9). It is doubtful, however, whether the cow is a photo-periodic or thermoperiodic animal, and the seasonal milk-productivity rhythm is due to the injurious effects of overheating an animal not adopted to cope with hot weather.

11.6.5: Artificial cooling of non-sweating animals in hot weather. Since overheating in non-sweating animals is due to lack of skin moisture for vaporization, the obvious method for cooling would seem to be external application of moisture. Swine naturally resort to mud wallows for moisture in the desirable form of mud. When given the opportunity, cattle stand in cool water during hot weather, and sheep migrate to higher altitudes.

Under commercial conditions these summer devices are not usually accessible. Commercial air conditioning is too expensive, although consideration is given it¹¹². Dairymen install powerful fans on the theory that fans cool cows as they do men. It is obvious from what has been said that this theory cannot be altogether true. Fanning cools sweating animals because it accelerates the vaporization of the sweat; but fanning cannot increase the

¹¹² Kelley¹⁰⁶

vaporization rate if the skin is dry and cannot cool the animal unless the environmental temperature is lower than the skin temperature. The (sweating) dairyman's assumption that because he is cooled by fans the (non-sweating) cow is likewise cooled is understandable but not penetrating. Fans are not likely to increase the vaporization rate from the respiratory passages because the moisture from these sources is already fanned by the respiratory movements.

It is true that even non-sweating animals give off some moisture from the skin¹¹³; Jersey cows are said¹⁰¹ to give off about 1 pound of moisture per hour by non-sweating methods. However, this non-sweating moisture, referred to as diffusion or osmotic moisture⁷⁵ is probably unimportant in body-temperature regulation in hot weather (Fig. 11.17).

The foregoing discussion suggests the desirability of employing some substitute for sweat glands, perhaps some spongy, porous covering, such as rubber or acetate sponge, which holds moisture and permits good air circulation. A cover of some such fabric as jute may be useful to protect the rubber against sun and manure and assist with absorption and vaporization of the moisture. We investigated in a preliminary way the influence of wet, porous rubber sponge blankets on the respiration rate (the best index of a non-sweating animal's comfort with respect to temperature) of sheep and cows, with promising results, shown in Figs. 11.19 and 11.20.

Fig. 11.21 shows the results for sheep. Wet blankets were put on sheep A and B at 10:30, while sheep C and D served as controls. In the blanketed animals, the respiration rate immediately dropped from its initial level of about 190, to 160, 150, and finally 145. By 1 o'clock the blanket began to dry, and the respiration rate began to rise. When the blanket was removed, the respiration rate promptly attained its initial level. The environmental temperature during this observation was between 90° and 100° F (32° to 38° C).

Fig. 11.22 exhibits similar results for cattle. Four cows were observed. Cows 731 and 740 were not blanketed; cow 731 had a powerful fan blowing over her, while cow 740 had no fan. Cows 712 and 677 had wet sponge blankets; 712 had in addition a fan blowing over it; 677 had no fan. Under the given conditions, the fans apparently did not help either the blanketed or non-blanketed animals. Indeed, in the non-blanketed animals, the fan seemed to increase the respiration rate for a time, perhaps by forcing the hot air into the animal's skin. There is no doubt, however, that the wet blankets reduced the respiration rate considerably. It appears from these preliminary observations that a wet-porous blanket might maintain the comfort and productivity of non-sweating farm animals in the hot season of the year, thus preventing an enormous aggregate waste from declined productivities during July, August, and September.

11.6.6: Fever: heat exhaustion: heat cramp: ventilation and air-conditioning: exercise: diet: clothing: and weather. Most fevers reflect disturbance of the normal equilibrium between thermogenesis and thermolysis, a change in level of thermostatic control.

¹¹³ Richardson⁷⁴

Malarial fever illustrates a different situation. Shivering during the chill increases heat production about three-fold, from about 80 to 230 Cal per hour¹¹⁴; yet heat elimination is not increased. The result is a rise in body temperature of about 2° C in one-half hour. At the beginning of the chill, the body temperature (of mouth or rectum) is normal, but the skin temperature is below normal, which gives the *sensation* of chill and leads to shivering. This illustrates the complicated temperature-gradient configuration. There may be a rise of temperature in one part and a decline

Fig. 11.21. The influence of a wet rubber-sponge blanket on the respiration rate of sheep.

in another, but one *feels* the temperature only of the part (skin) which is capable of signalling to the brain. The liver has a temperature which is normally several degrees above the rectal temperature, while the mouth temperature is about 1° C below the rectal.

The upper survival temperature limit for fever in man¹¹⁵ is 107° F (41° C) but may rise in pre-mortal states to 110° F (43° C). Each disease has its

characteristic temperature curve: the temperature in malaria fluctuates; the temperature in pneumonia rises steadily until the crisis is reached. Fever may be produced not only by disease organisms, but also by chemical pyrogens, such as by dinitrophenols, thyroxine, and also by bacilli, dead or alive, and by other foreign bodies¹¹⁶.

Elevation of body temperature may result from a hot environment or from excessive heat production consequent to hard muscular exercise. Such elevation of body temperature is often followed, especially in the aged, by collapse variously referred to as *heat exhaustion*, *heat stroke*, and *sun stroke*. The collapse may be due to the high temperature but more often to circulatory

Fig. 11.22. The influence of a wet rubber-sponge blanket, and of fanning the uncovered and sponge-covered animals, on the respiration rate of cattle (Holsteins).

failure¹¹⁷, partly as result of peripheral vasodilation with consequent necessity of accelerated circulation of the diminished available blood (the blood that is released for cooling at the body surface is, for the moment, unavailable for oxygen transport).

It is interesting to note that ascorbic acid (vitamin C) is excreted in sweat¹¹⁸; hence the greater need of vitamin C in profusely sweating persons. No doubt,

¹¹⁸ Bernstein, R. E., *Nature*, **140**, 684 (1937).

the same holds true for other water-soluble vitamins and salts, which may lead to other disorders such as *heat cramp*.

A dramatic hot-weather disability in sweating animals in *dry* environment is *heat cramp*. The outstanding symptom is pain in the muscles, including the heart muscle. This results from excessive loss of common salt in the sweat¹¹⁹. This difficulty is prevented by drinking water containing¹¹⁹ 0.1 per cent sodium chloride, and acute cases are cured by injection of large amounts of normal saline. It has been suggested to drink water containing 0.012 per cent KCl and 0.018 per cent NaCl. Farm animals that have access to salt probably never develop heat cramp, because, unlike man, animals develop a salt craving, and consequently satisfy the salt need.

However, administration of salt is not helpful in heat stroke, previously described, because the underlying difficulty is not salt loss but high body temperature and consequently high pulse rate (above 135).

For hot-weather comfort one should obviously avoid conditions that increase heat production and adopt those that protect against direct sunlight and increase heat dissipation. Heat production is, of course, increased by muscular exercise and high-protein food (*SDA*).

Protection against sun radiation includes such devices as wearing sun helmets; protecting windows by aluminum-painted awnings or venetian blinds—placed on the outside; protecting the roof, if flat, by a layer of water, otherwise by light-colored paint, preferably aluminum paint which absorbs only 40 per cent of the radiations as contrasted to asbestos shingles, unpainted wood, stone, brick, red tile, which absorb 70 per cent, and black surfaces, as slate or tar, which absorb 90 per cent of the radiations¹²⁰. Water sprayed over the roof, and attic ventilation help to dissipate the absorbed heat.

The temperature of a room may be lowered directly by vaporization. The War Department uses¹²¹ a cooler which consists of a metal cabinet filled with a fine porous substance, such as excelsior, thoroughly wet, and placed in the window. A fan on the roomside of the cabinet draws the wet air through the room. Evaporation of this moisture lowers the room temperature. This method, no doubt excellent for hot, dry climates, would not seem useful for hot, humid climates. Hot weather comfort depends on low relative humidity¹²².

¹²² Relative humidity is the ratio of water vapor in the air to the maximum it can hold. As the water-holding capacity declines with fall of temperature, decline of temperature leads to condensation of moisture. Thus at 68° F (20° C) air holds 7.5 grains water

The importance to sweating animals of the effect of relative humidity on the cooling properties of air in hot weather may be inferred from the fact that while a man can hardly bear an environmental temperature of 98° F (37° C) in a saturated atmosphere, he can withstand for a short time a temperature of 150° F (65° C) in perfectly dry, briskly-moving air. Hence for practical comfort in hot weather, briskly moving dehumidified air may be as good as an atmosphere chilled by refrigeration. Chilled air often gives a feeling of stuffiness, and does not meet the need for a desirable variety in air movement and temperature, simulating the natural conditions of play of the wind, which invigorates and gives a feeling of freshness. As previously noted, for non-sweating animals briskly moving air may not be helpful, unless the surface of the animal is kept moist by some such device as a wet blanket or by sprinkling.

Some of the foregoing hot-weather suggestions may be reversed for comfort in cold weather. In cold weather foods or feeds having a high *SDA* effect (such as high protein) are desirable; so is exercise. Poorly insulated walls and ceilings give an unpleasant sensation of cold beyond the expectation of the physical temperature of the atmosphere. This is because cold walls cause excessive heat loss by radiation and one does not feel comfortable when the heat lost by radiation exceeds 50 to 60 per cent of the total heat produced. Room air at 60° F with walls at 80° F *feels*¹²³ as warm as room air at 80° F with walls at 60° F. Hence the importance for winter comfort of having well-insulated walls and ceilings. In frame houses walls are insulated by filling studding spaces with insulating material and using tightly fitting storm sashes.

High humidity in cold weather increases the feeling of cold because it increases the conductivity of clothing.

Clothing furnishes man with a private climate. The degree of privacy depends on the amount of air that the fur, feathers, or clothing can hold stationary. Fur is warm because of the great amount of air it holds. A good fur is composed of 98 per cent air and 2 per cent hair. The amount of air held in the fur or feathers is controlled by the animal by holding the hairs more or less erect. The more erect, the more air. The following figures give an idea of the relative conductivity (inverse of insulation) of air, hair, feather, and some fabrics¹²⁴: air, 100; feathers, 108; knitted wool, 122; smooth silk fabric, 129; hair, 143; smooth cotton fabric, 152; linen, 218; water, 2000.

From the high conductivity and latent heat of water, the importance of

vapor; at 50° F (10° C) it holds only 4.2 grains, and the remaining 3.3 grains drops out as liquid water. Hence cold walls tend to be wet. At 70° F (21° C), 30 to 60 per cent relative humidity is most comfortable.

knowing the relative absorption and vaporization properties is evident. Yarn construction and weave make a great deal of difference. As regards water absorption, the following are probably in decreasing order: sponge rubber, linen, cotton, silk, jute. Little is known concerning the relative ease with which moisture is given off by various substances. All that can be said is that densely woven materials do not absorb moisture. Feathers and wool are naturally covered with oil, which repels moisture. For hot-weather wear, the clothing should be porous so as to absorb moisture from the skin and then give it off slowly for comfortable cooling of the body. This reasoning justifies woolen underwear in hot weather.

It is interesting to note that under the same environmental condition of 72° F (22° C), relative humidity 30 per cent, and air movement 20 feet/minute, the mean skin temperature of woman is 2° F lower than of man, and that of the hands and feet 5° F lower. Under these conditions men feel comfortable and women feel cool. Room temperatures of 71.5° F for men and 76° F (25° C) for women give the same skin temperature (92° F) and comfort to both.¹²⁵ In the nude and in basal condition men have a slightly higher skin temperature than women,¹²⁶ probably due to differences in subcutaneous fat. In summer weather of 94° F (34° C) the skin temperature is the same in both.

These sex differences in skin temperature and comfortable feeling seem to be due mostly to sex differences in clothing worn and, to a slight extent, to differences in subcutaneous fat. In general, when men and women wear the same clothing, the skin temperature and comfortable feeling are virtually the same for both. With minimum clothing, 82° F (giving a mean skin temperature of about 93° F), satisfies both equally well.

Fairly hard muscular work, such as mining and farming, is best done not at thermoneutrality but at the relatively low temperatures of 40° to 65° F (4° to 18° C). One cannot, however, speak of temperature independently of humidity and air movement, since the three are interrelated in their physiologic effects. The "effective temperature" represents physiologic effect¹²⁷. Pending the more general adoption of the effective temperature scale, 65° F (18° C) is currently quoted as the minimum suitable temperature during rest for man, but the most comfortable condition is nearer 75° F (24° C), depending on the season (acclimatization).

Productive farm animals are in the condition of hard-working men, doing best below 65° F (18° C), and the published "critical temperatures" for farm animals have no bearing on the temperature of maximum productivity and efficiency. The serious agricultural problem in most parts of this country is not how to keep adult farm animals warm in winter but how to keep them cool in summer.

11.7: Summary. The major concerns of this chapter are: (1) the mechanism of homeothermy, and (2) the influence of environmental temperature

on the speeds and efficiencies of life processes in animals, with applications to calorimetry and animal husbandry. Brief consideration is also given to the influence of environmental temperature on the physiologic reactions of man.

Homeothermy is achieved by a number of devices including: (1) cooling by vaporization of moisture from the respiratory passages and skin (a curious fact in this connection is that the rate of respiration in non-sweating animals increases according to the Van't Hoff-Arrhenius equation with respect *not* to body temperature, as might be expected, but to environmental temperature); (2) developing insulating coatings (fat, fur, etc.) on approach of the cold season; (3) dilation or contraction of surface blood vessels by nervous mechanisms, thus exposing the blood to the surface for cooling, or removing from the surface for protection from cold; (4) changing the blood volume and blood concentration; (5) varying the rate of production of metabolic hormone (acetylcholin, adrenaline, thyroxine); and (6) changing tonus of muscles, thus changing the rate of heat production; (7) adopting certain behavior patterns (huddling, rolling up, spreading out, etc.).

According to their ability to withstand high environmental temperature, homeotherms are divided into (1) profusely sweating animals, exemplified by men, horses, mules, and asses, who can withstand great heat, particularly in dry, moving air; (2) slightly sweating (or panting) animals, exemplified by cattle, sheep, swine, dogs, cats, rats, and rabbits, unable to withstand great heat.

When a profusely sweating animal is placed in a hot environment it responds by sweating, and by sending its blood to the moist surface for cooling by vaporization of the sweat. This reduces the blood volume needed for carrying oxygen to the tissues. To compensate for this deficiency, the heart pumps faster, that is, the *pulse rate rises*. When a slightly sweating animal is placed in a hot environment, it responds not so much by sweating as by panting, that is, by a rapid but shallow respiration rate. The skin is not cooled because it is relatively dry, and the blood is sent from the hot skin to the interior, with the result that the *pulse rate declines*. As the increased respiration rate in hot weather does not increase the vaporization rate to the same extent as sweating does, the slightly sweating animal becomes overheated at relatively low temperatures, with consequent increase in heat production (maintenance cost), decrease in productivities, and decrease in efficiencies of the productive processes. Practical suggestions are presented for cooling non-sweating animals in hot environments by the use of wet, porous, sponge-and-fabric blankets as substitutes for sweat glands.

Beginning with the "comfort zone", farm animals, especially of the non-sweating class, are very much less sensitive to declining than to rising temperature. Thus the productivities, efficiencies, and comfort of farm animals are not reduced by decline in the environmental temperature from the comfort zone of 60° to 70° F (15–21° C) to perhaps 0° F, while raising the temperature

above 80° F overheats and seriously reduces the productivities of non-sweating farm animals, and to a less extent of sweating animals. Homeotherms have much more powerful methods for protection against cold than heat.

Similarities and differences between the influence of environmental temperature on productivities and efficiencies of homeotherms and poikilotherms are brought out, with special reference to the operation of the Van't Hoff law in the two classes of animals, as illustrated by decline in metabolism in poikilotherms and rise in homeotherms when the temperature falls below about 80° F or 27° C.

Chapter 12

Methods in Animal Calorimetry

The modern era of the science of nutrition was opened by Lavoisier in 1780. Lavoisier (1743–1794) was the first to recognize that animal heat was derived from the oxidation of the body's substance and he compared animal heat to that produced by a candle. The form of Lavoisier's apparatus is illustrated in two drawings made by Madame Lavoisier. But the method is unknown, for on May 8, 1794, Lavoisier was executed by the Paris Commune. *Graham Lusk*

12.1: Principles. The two major biocalorimetric categories are *direct* and *indirect*. In the absence of anaerobic, endothermic, and other unusual reactions in which the caloric equivalents of O_2 and CO_2 are unknown, the results of the two methods are in substantial agreement. Both are equally simple in principle. In practice, since the direct method is much more expensive and complicated, it is rarely used, except when unusual metabolic reactions are suspected and the caloric values of O_2 or CO_2 are in doubt.

Both direct and indirect methods were originated by Lavoisier^{1, 2} in a year memorable in American and French history, 1777. Lavoisier then introduced the essentially modern chemical nomenclature, especially as it relates to oxygen in life processes, and demonstrated that living involves oxidation. He defined life as a chemical process: "*La vie est une fonction chimique*". Lavoisier is thus the founder of modern nutrition as well as of modern chemistry.

12.1.1: Direct calorimetry. Lavoisier and Laplace confined a guinea pig in a chamber containing a given weight of ice, and estimated the heat production from the amount of ice melted. The carbon dioxide exhaled was also collected. They found that the melting of a given weight of ice corresponds to the exhalation of a definite amount of carbon dioxide. They also measured the heat production of a rabbit by the temperature rise in a given volume of water surrounding the animal chamber. Modern animal calorimeters apparently differ only in detail from the Lavoisier models.

About $\frac{1}{4}$ of the body heat is dissipated by moisture vaporization which can be measured by absorption in such reagents as H_2SO_4 , $Mg(ClO_4)_2$, and so on. About $\frac{3}{4}$ of the heat is emitted by radiation, conduction, and convection, and can be measured by absorption in water. The total heat produced is the sum of the two.

ire de la chimie", 1780.

² Jones, D.,

The modern water calorimeter is a well insulated box, just large enough to hold the subject. The inside of the box is usually lined with copper, the outside with zinc. The two are connected by resistance thermometers so as to keep the outside zinc lining at the same temperature as the inside copper lining, thereby avoiding loss of heat from the calorimeter.

The chamber interior is kept at a constant temperature by water circulating through pipes attached to the ceiling. The heat absorbed by the water is computed from the amount of water flowing per unit time, and from the temperature difference between incoming and outgoing water. Thus, if 20 kg water flows per hour, and the temperature of the water is 1°C higher at the exit than at the entrance, the heat absorbed by the water is 20 Cal. The heat of vaporization is determined by the weight increase of the water absorbers. The vaporization of 1000 grams (1 liter) of moisture is equivalent to 580 Cal. heat dissipation.

In compensation calorimetry³ one chamber holds the animal while another, similar chamber has electric-resistance wires made to produce exactly the same amount of heat as that emitted by the subject in the other chamber. In differential calorimetry⁴ the rate of total heat supply is maintained constant, first with the calorimeter empty, second with the animal inside.

The first modern respiration calorimeter was built by Max Rubner for a dog. It was provided with an open-circuit (Pettenkofer-Voit) apparatus. In this way, Rubner⁵ demonstrated in 1894 that the heat measured by direct calorimetry is in substantial agreement with the heat computed from indirect calorimetry. This was amply confirmed.⁶

12.1.2: Indirect calorimetry. Indirect calorimetry was first used by Lavoisier and Laplace, who demonstrated that the exhalation by a guinea pig of a given quantity of carbon dioxide corresponds to the melting of a given weight of ice surrounding the animal. Indirect calorimetry is thus based on the fact that, normally, O₂ consumption and CO₂ production are closely correlated with heat production. This may be illustrated by the oxidation equation for carbohydrate previously discussed (Ch. 2).

The equation states in effect that the consumption of 6 mols (that is $6 \times 24.4 = 134.4$ lit) O₂, or the production of 6 mols CO₂, in the oxidation of a mol hexose (180 g) yields 678 Cal; therefore, the consumption of 1 lit O₂, or the production of 1 lit CO₂, yields for *carbohydrate oxidation* 5.047 Cal ($5.047 = 678/134.4$). The heat production may then be measured by liters O₂ consumed, or CO₂ produced, multiplied by 5.047. It may be shown

in similar manner that for the oxidation of *mixed fat*, 4.69 Cal is generated per liter O₂ consumed, or 6.6 Cal per liter CO₂ produced.

For the oxidation of *mixed protein* 4.82 Cal is generated per liter O₂ consumed or 5.88 Cal per liter CO₂ produced. (Pflüger's "caloric coefficient of oxygen" is the ratio of heat produced in Calories to O₂ consumed in g, which is about 3.5 for carbohydrates, 3.3 for fat, and 3.2 for protein oxidation.)

Since the caloric equivalent of O₂ consumed and CO₂ produced varies with the nature of substance oxidized, it is theoretically necessary to know the composition of the fuel mix (carbohydrate, fat, protein) oxidized.

The amount of protein oxidized is computed from the urinary N excretion. Assuming that protein contains 16 per cent N and that all urinary N is derived from protein oxidation, the protein catabolized is estimated by multiplying the urinary N by 6.25 ($\frac{100}{16} = 6.25$). These assumptions are sufficient, although not literally true

Thus only $\frac{1}{3}$ to $\frac{1}{2}$ of potato N is in protein form. Alfalfa, as well as potato, contains many non-protein nitrogenous compounds, such as stachydrine, choline, adenine, trimethylamine, and betaine. Animal protein, such as casein, serum globulin, serum albumin, and also legume-seed protein contains 16 per cent N (conversion factor 6.25); cereal proteins contain 17-18 per cent N (conversion factor 5.8 to 5.9); oil-seed proteins contain 18-19 per cent N (conversion factor 5.3).⁷

The relative amounts of fat and carbohydrate oxidized are determined from the non-protein *respiratory quotient*, R.Q. The R.Q. is the ratio of mols or volumes of CO₂ produced to mols or volumes O₂ consumed. For the oxidation of carbohydrates the R.Q. is unity, as shown by the foregoing oxidation equation for carbohydrate,

$$\frac{6\text{CO}_2}{6\text{O}_2} = 1.00$$

Conversely, when the non-protein R.Q. is 1.00, it is assumed that carbohydrate is oxidized.

The R.Q. for *mixed fat* is 0.71, although each fat has its distinctive R.Q. The short-chain fats have an R.Q. nearer 0.8:

$$\text{R.Q.} = \frac{30}{37} = 0.8$$

The long-chain fats have an R.Q. nearer 0.70:

$$\text{R.Q.} = \frac{102}{145} = 0.703$$

⁷ Jones, D. B., U. S. Department of Agriculture Circular, 183, 1931.

The R.Q. for *mixed protein* is 0.81, although, as fats, each protein and amino acid has its distinctive R.Q. The oxidation of the amino acid alanine may yield an R.Q. of 0.83. Thus

$$\text{R.Q.} = \frac{5}{6} = 0.83$$

However, other amino acids and other conditions (Ch. 4) may yield different values.

TABLE 12.1.—Thermal Equivalents of O₂ and CO₂ and the Corresponding Percentages of Fat and Carbohydrates Oxidized for Different Respiratory Quotients (R.Q.)^a.

Table 12.1, after Lusk, originally (1901) after Zuntz and Schumberg, indicates the percentages of fat and carbohydrates oxidized and the caloric equivalents of O₂ and CO₂ for different non-protein R.Q. values; and Table

^a See Lusk, G., "The Science of Nutrition," Chapter 8, 1928. See also Zuntz, N., and Schumberg, H., "Studien zur einer Physiologie des Marsches Berlin," p. 361, 1901.

12.1A illustrates the method of computing heat production employing the R.Q. and urinary-nitrogen methods.

In most cases it is not necessary, often not even advisable, to employ the elaborate method given in Table 12.1A for estimating metabolism because the R.Q. does not always have the rigorous significance given it in the above considerations and in Table 12.1.

Thus, cattle and other ruminants produce huge quantities of CO₂ in the digestive tract (Ch. 2) by anaerobic bacterial fermentation and by liberation

TABLE 12.1A.—Computing Energy Metabolism and Non-protein R.Q. from the Urinary N* and Respiratory Exchange.
(Data re-arranged from Lusk's book, p. 69 (1928) on a 12.75-kg dog)

(1) G urinary N excreted/hr	0.136
(2) G "protein" oxidized (1×6.25)	0.850
(3) G CO ₂ associated with protein oxidation (1×9.35)	1.272
(4) G O ₂ associated with protein oxidation (1×8.49)	1.15
(5) Liters CO ₂ associated with protein oxidation ($3 \times .5087$)	0.647
(6) Liters O ₂ associated with protein oxidation ($4 \times .6998$)	0.805
(7a) Total g CO ₂ exhaled/hr	6.75
(7b) Total liters CO ₂ exhaled/hr ($7a \times 0.509$)	3.44
(8a) Total g O ₂ consumed/hr	6.17
(8b) Total liters O ₂ consumed/hr ($8a \times 0.6998$)	4.32
(9) Liters non-protein CO ₂ ($7b - 5$)	2.79
(10) Liters non-protein O ₂ ($8b - 6$)	3.52
(11) Non-protein R. Q. ($9/10$)	0.79
(12) Overall R.Q. ($7b/8b$)	0.80
(Indicating that overall and non-protein R.Q. are not likely to differ much.)	
(13) Caloric value/lit O ₂ at given R.Q. (0.79)	4.789
(14) Non-protein Calories (10×13)	16.86
(15) Protein Calories (1×26.5)	3.60
(16) Total Calories by indirect calorimetry ($14 + 15$)	20.46
(17) Calories by direct calorimetry	20.92
(18) Difference between direct and indirect calorimetry, 0.46 Cal, or 2.3 per cent	

* 1 g urinary N derived from protein is associated with the consumption of 5.91 liters or 8.49 g O₂ and the production of 4.76 liters or 9.35 g CO₂, and production of 26.5 Calories. 1 g O₂ = 0.6998 lit. 1 g CO₂ = 0.509 lit. The oxidation of 1 g fat (tripalmitin) is associated with consumption of 2.01 liters O₂ and production of 1.41 liters CO₂; the oxidation of 1 g starch is associated with the consumption of 0.83 lit O₂ and production of 0.83 lit CO₂. The non-protein R.Q. is estimated by deducting the liters of protein CO₂ produced (g urinary N \times 4.76) from the total liters CO₂ produced, and the liters of protein O₂ consumed (g urinary N \times 5.9) from the liters of total O₂ consumed.

of CO₂ from bicarbonates. This extra-metabolic CO₂ cannot be distinguished from the respiratory-metabolism CO₂. Under such conditions the R.Q. has no metabolic significance, and, of course, the quantity of CO₂ production cannot be taken as a measure of metabolism. Under such conditions the rate of oxygen consumption is the best measure of heat production. Incidentally, under such fermentation conditions, direct calorimetry would not indicate with precision metabolism in the body proper, as it would include the heat of fermentation.

Excess CO₂ may also be liberated under conditions of acidosis, such as

ketosis, and of overventilation in general. On the other hand, CO_2 may be stored under conditions of alkalosis. A low R.Q. may also result from incomplete oxidation, formation of sugar from protein, fat, and other substances.

Moreover, as shown in Table 12.1, while the range in caloric equivalents of CO_2 is relatively wide, from 5.0 to 6.7 Cal per liter, the range of caloric equivalent of O_2 is relatively narrow, from 4.7 to 5.0 Cal per liter, an extreme range of 7 per cent, or a deviation of about 3.5 per cent from the mean value (when the R.Q. is 0.82), which is within the limits of experimental error in metabolism measurements.

Furthermore, since the average R.Q. of protein is 0.82, which corresponds to the average caloric value of O_2 of 4.825 Cal per liter, no correction need be made for protein metabolism when measuring energy metabolism by oxygen consumption. (Benedict reported 4.7 Cal per liter O_2 for protein.)

The simplest and, under normal conditions, perhaps the most accurate, method for measuring energy metabolism is, then, by the rate of oxygen consumption, as fed from a calibrated oxygen container, and computing the heat production by the caloric value of oxygen, *e.g.*, 4.825 Cal/liter, corresponding to an R.Q. of 0.82.

The basal metabolism in humans is measured about 12 hours after the preceding meal, when the R.Q. is about 0.82.

We⁹ have adopted this method for measuring the energy metabolism of farm animals—cattle, horses, sheep, swine, and goats; and we have even measured the metabolism of elephants by this method¹⁰, the results of which agreed satisfactorily with those published later by Benedict¹¹. Let us describe this method of measuring metabolism in detail, after a brief summary.

To summarize, energy metabolism may be measured by (1) *direct calorimetry*, by absorption of the heat in a water jacket and collecting the expired moisture or by related methods; (2) *indirect calorimetry*, by measuring O_2 consumption alone, or in combination with CO_2 production and urinary-nitrogen excretion. For most purposes—when the reactions are not endothermic or partly anaerobic and the caloric equivalent of O_2 is known—indirect calorimetry is more reliable than direct, and the measurement of O_2 consumption alone gives as good, sometimes better, results¹² than measuring CO_2 production and the R.Q.

¹² For objections against O_2 consumption as index of metabolism and for the advantages of CO_2 as metabolic index, see Adams, T. W., and Poulton, E. P., *Guys Hosp. Repts.*, 85, 56 (1935), and 87, 107 (1937). King, J. T., *Johns Hopkins Hosp. Bull.*, 32, 277 (1921). Rabinowitch, I. M., and Bazin, E. V., *J. Canadian Med. Assn.*, 16, 638 (1926). Adams and Poulton: "CO₂ production is more constant with R.Q. change than is O₂ consumption; range in heat value of CO₂ is only apparent, not real, due to interconversion of fat and C.H.; CO₂ is a direct combustion product while changes in O₂ may be due to changes in fat—C.H. interconversions."

The *indirect* biocalorimetric methods are divided into (1) *closed-circuit type* (Regnault and Reiset, 1849), involving rebreathing the same air after removing its CO_2 by circulating through alkali [soda lime, $\text{Ba}(\text{OH})_2$ solution, etc.] and replacing the consumed O_2 by fresh O_2 ; (2) *open-circuit type* (Pettenkofer and Voit, 1862), involving the circulation of outside air through the system. Examples of each system of measuring metabolism are described below.

12.2: Methods of indirect calorimetry. Since direct biocalorimetry is not often used, the discussion is confined to indirect methods.

12.2.1: Closed-circuit spirographic-mask method for farm animals. This method is illustrated in Figs. 12.1 to 12.7. Its use for measuring human "basal" (or "standard") metabolism was made generally known by Benedict¹³ and associates. It consists in connecting the pulmonary system of the subject to an oxygen spirometer, and measuring the rate of oxygen consumption by the rate of decline of the oxygen bell. As shown in Fig. 12.1a, after Roth¹³ and Collins¹⁴, the air is circulated freely through the porous soda lime in one direction by the valves, *V*. The oxygen bell, *B*, which floats freely in the water seal, is counterbalanced by a weight, and so will not rise or fall except when acted upon by the circulating air. The decline of the bell is recorded graphically on the kymograph drum, *K*. The rate of oxygen consumption is computed from the slope of this graphic record.

Note from Fig. 12.3 to 12.6 that the animals are entirely at ease in natural positions, completely under the operator's control. There is thus no problem in "correcting" for standing and for other uncontrolled activities encountered by the use of the respiration-chamber method of measuring metabolism.

The clock-kymograph (*K* in Fig. 12.1) records the rate of oxygen consumption graphically. A typical graph is shown in Fig. 12.7. Note that the slope, not necessarily the absolute decline, in the oxygen bell, is used for computing the rate of O_2 consumption.

The oxygen bell (*B* in Fig. 12.1) is of a size to produce an oxygen-consumption line of reasonable slope (Fig. 12.7). The oxygen bell used for human metabolism by the Benedict-Roth method has a volume of 20.73 cc per 1 mm height. This oxygen volume has a caloric equivalent of 0.1 Cal (under STP conditions, assuming an R.Q. of 0.82 with a caloric equivalent of 4.825 Cal per liter). This bell size was adopted to facilitate computation. Roth measured the decline in slope for a 6-minute interval: a 1-mm slope per 6-minute interval corresponds to 0.1 Cal per 6 minutes, or 1.0 Cal per hour. Likewise, a 50-mm rise in 6 minutes corresponds to a heat production of 50 Cal per hour. Table 12.2 presents the relation between diameter, cross-section area, and cc per mm height of oxygen bell employed in our work.

When using the Benedict-Roth size spirometer the slope of the spiograph

¹³ Benedict, F. G., and Collins, W. E., *Boston Med. and Surg. J.*, **183**, 449 (1920); Roth, P., *Id.*, **184**, 222 and 228 (1921); **186**, 457, 491 (1922).

¹⁴ Collins, W. E., 555 Huntington Ave., Boston, Massachusetts, maker of metabolism apparatus.

in mm per 6 minutes is multiplied by a factor to reduce it to standard temperature, pressure, and humidity (see Table 12.3). The resulting value corresponds to the heat production in terms of Cal per hour. If there is a temperature rise in the oxygen bell during the 6 minutes, $\frac{1}{2}$ mm per $^{\circ}\text{C}$ is

Fig. 12.1a—Benedict-Roth-Collins clinical metabolism apparatus.

added to the rise of the O_2 consumption line before the other computations are made. The oxygen-spirometer method for measuring metabolism was originated (1887) by Fredericq¹⁵ and perfected by Benedict and associates¹³ in the United States and by Krogh¹⁶ in Europe.

¹⁵ Fredericq, L., *Arch. de Biol.*, **3**, 687 (1887); also in "Elements de physiologie humaine," 2nd ed., 1888, and in "Manipulations de Physiologie."

¹⁶ Krogh, A., *Boston Med. and Surg. J.*, **189**, 313 (1923).

As previously noted, the advantage of using this graphic spirometer method for measuring ruminant metabolism is that the digestive-tract CO_2 exhaled by these animals is absorbed in soda lime (Fig. 12.1a) and is thus eliminated as a complicating factor.

Fig. 12.1b—"We employed oxygen-bell sizes $\frac{1}{10}$, $\frac{1}{5}$, $\frac{1}{2}$, 1, 2, 4, 8, 16, and 32, depending on the size of the animal. Size 1 is that used in the standard Benedict-Roth apparatus (volume of 20.73 cc per mm height) and the others are multiples ($\frac{1}{10}$, $\frac{1}{5}$, etc.) of the #1 size. The given numerical values are here tabulated and plotted against the bell size on a logarithmic grid."

This method would indeed be ideal for ruminants except for the fact that they also exhale some CH_4 (after its absorption into the blood stream from the rumen¹⁷) which may accumulate in the oxygen bell, so that the decline

in the oxygen bell due to the consumption of its oxygen will be less by the volume of CH_4 accumulated. However, as shown in Fig. 12.9a, the error introduced thereby is relatively slight, perhaps 3 per cent, 8 to 12 hours after feeding. The oxygen consumption was measured regularly before the morning feeding. The graphic spirometer method, of course, involves only a part of the CH_4 eliminated, not that eliminated by rectum or regurgitated by the esophagus, because such more or less sudden gas elimination is graphically recorded, and the metabolism is measured by the smooth *slope* of the graphic record, not by the absolute change in height of the oxygen bell.

Fig. 12.8a presents observations on the relative heat production in goats obtained by the spirometer method which involves the CH_4 error (B) and by the open-circuit method which does not involve the CH_4 error (A); also by the spirometer method after correcting for CH_4 by analysis of the spirometer atmosphere for CH_4 (C, D).

Fig. 12.7—A six-minute spirogram from which the rate of oxygen consumption is computed.

Fig. 12.8b presents data on methane production obtained by the spirometer open-circuit methods on both cows and goats; it demonstrates a very rapid decline in methane production following feeding. The methane error is inappreciable 48 hours after feeding; postabsorptive metabolism measured by the oxygen spirometer method does not suffer from the methane error.

12.2.2: Closed-circuit-chamber system for smaller animals¹⁸. As previously noted, the closed-circuit method was originated by Regnault and Reiset¹⁹. Fig. 12.10 represents the original Regnault-Reiset apparatus. The

writer has seen a modification of it used by Professor Otto Kestner in Hamburg. In this country Kleiber²⁰ uses a modification for measuring the metabolism of rats, and Winchester²¹ for chickens. We²² employed similar apparatus for small laboratory animals from mice to chickens. The following description is for Winchester's apparatus constructed in the writer's laboratory for the domestic fowl. One of the four independent respiration chambers is illustrated in Fig. 12.11a. Fig. 12.11b is a photograph of both our large (fowl) and small (rat) apparatus. At least the Mariotte bottles show clearly.

This apparatus consists of 4 parts: (1) constant-temperature cabinet; (2) burette system (8-liter capacity) consisting of three tubes (110 cm long), two large (7 cm in diameter) and one ordinary titration burette, 1 cm in diameter, all interconnected so that they have the same water level (1.0 cc in the burette corresponds to 74 cc in the entire burette system composed of the three tubes); (3) Mariotte bottle; (4) CO₂ absorbers. There are also auxiliary items, including pressure gauge; equilibrator, which adjusts temperature of water in Mariotte bottle to that of chamber, and O₂ concentration of the water to that prevailing at chamber temperature; O₂ spirometer, which keeps air out of the top of the Mariotte bottle by connection with pure O₂; rocking mechanisms; fans; and so on.

Because of the sensitiveness of gas volume to temperature change, the apparatus is kept in a constant-temperature cabinet. Four 100-watt electric lamps, which are connected to a relay switch controlled by a mercury-acetone thermo-regulator, together with two 10-inch fans, keep the cabinet (194 × 43 × 122 cm) temperature constant (at 30° C) within 0.1° C.

The rate of O₂ consumption is measured by the rise of the water in the burette. As the O₂ from the burette system is consumed, it is replaced by water which automatically flows from the Mariotte bottle whenever the pressure at the siphon tube outlet falls below that at the inlet. (In the Mariotte bottle the bottom of the O₂ inlet is at such a level that the pressure of H₂O above it plus the pressure of the air above the water level is equal to the pressure at the siphon tube outlet.)

The CO₂ is absorbed in the battery by a saturated Ba(OH)₂ solution, prepared by mixing 100 cc each of 2N KOH and molal BaCl₂. The Ba(OH)₂-solution battery consists of 2 sets of two flat-bottomed flasks (each 500 cc for chickens) joined near the bottom by a glass tube. The alkaline solution flows from one flask to the other, alternately drawing air from and returning it to the chamber (at the rate of 12 liters per minute).

The rate of O₂ consumption is easily and accurately measured by the rise of water in the burette. The CO₂ production is determined by titration of the standardized alkaline CO₂-absorbing solution. The R.Q. is computed from the CO₂ and O₂ values.

If the R.Q. is not needed, the rate of O₂ consumption is measured by reading the burette at 10-minute intervals until several successive readings check. In this manner the metabolism may be estimated in 1 to 1½ hours instead of the 2 to 4 hours required when the R.Q. is determined.

The O₂-consumption measurements do not begin until after the animal has been in the chamber for ½ hour, in order to (1) accustom the animal to the chamber, (2) bring the system to the standard temperature (30° C), (3) establish an equilibrium between the

Fig. 12.11c—Regnault-Reiset apparatus.

absorbing rate of the battery and the CO_2 -production rate. (The chamber air contains about 1 per cent CO_2 at the end of the first half, and this concentration remains approximately constant throughout the trial.)

Our rat-apparatus burette system has an O_2 capacity of 1 lit (1 cc in the graduate burette corresponds to 10 cc in the system; length of the burette, 106 cm). The chamber volumes are 1.0 to 1.2 liters. The temperature is controlled by 150-watt chromnickel resistance coils (instead of light bulbs.)

Fig. 12.12—Titration arrangement for the Regnault-Reiset apparatus.

The titration apparatus illustrated in Fig. 12.12 prevents CO_2 loss during titration, as any CO_2 lost from the absorber solution is held in the cylinder where it can be measured. The titrating acid is liberated below the surface of the alkaline-absorber solution. A thymol blue-cresol red solution affords a sharp color change from purple to orange-yellow at the end point.

Computation example: A fowl was placed in a chamber at 7 p.m. and the first oxygen reading was made half an hour later. In the following example only the initial and end readings are given.

Volume of chamber air + tubes and absorbers.....	7.00 liters
Volume of bird (the figure for weight in kilograms is taken to represent volume of the animal).....	1.73 "
Chamber + tubes and absorbers + volume of animal.....	5.27 "

Oxygen Consumption								
1	2	3	4	5	6	7	8	9
Time	Burette Reading	Volume of gas in burette	Burette Vol. + air in the chamber, absorber, etc.	Temperature (°C)	Barometric Pressure	Factor for Volume	Volume (Standard)	Volume (Difference)
7:30	93.1	7.26	12.53	30.0	74.7	.847	10.61	
10:00	52.0	4.31	9.58	30.0	74.7	.847	8.11	2.50
O ₂ consumed		2.95	2.95					
O ₂ consumed (corrected) = 2.50 liters (2.95 × .847)								2.50
O ₂ consumed in 2.5 hours.....							2.50 liters	
O ₂ consumed in 1.0 hour.....							1.00 liter	

CO₂ Production

KOH solution in battery.....	200	cc
BaCl ₂ solution in battery.....	200	cc
This was found to be equivalent to.....	166.5	cc of 2.11N HCl
HCl used in titration.....	68.7	cc of 2.11N HCl
CO ₂ absorbed equivalent to.....	97.8	cc of 2.11N HCl
1 cc. of 2.11 N HCl is equivalent to.....	23.63	cc of CO ₂
In 3 hours CO ₂ production was.....	2311.0	cc of CO ₂
In 1 hour CO ₂ production was.....	770.3	cc of CO ₂ or 0.77 liter

$$R.Q. = \frac{CO_2/hr}{O_2/hr} = \frac{0.77}{1.00} = 0.77$$

Heat Production

For R.Q. 0.77, a liter of O₂ is equivalent to 4.8 Cal = 4.8 Cal/hour

Body weight of the fowl = 1.729 kg = 1.48 kg^{0.73}

Possible objections to this Regnault-Reiset method are: (1) it does not permit measurement of the water vaporization, as is possible by the Haldane gravimetric method which will be described presently; (2) the atmosphere is saturated with moisture which, at higher environmental temperatures, tends to depress the heat regulation of the body by water vaporization.

12.2.3: Open-circuit gravimetric method for smaller animals. This method, devised by Haldane²³, is the easiest to set up and to maintain, and also to operate, especially if the R.Q. is not needed. Depending on available size of scales, it may be used for animals ranging in weight from mice to large rabbits. We used it for fowl²⁴ (Fig. 12.15), rabbits, and rats²⁵ (Figs. 12.16 and 12.17).

The principle may be explained by referring to the original Haldane design, Fig. 12.14. This consists of a respiration chamber, *Ch*, which may be an ordinary fruit jar, in which the animal is kept, and several H₂O and CO₂ absorbers. The H₂O is usually absorbed by concentrated H₂SO₄ (in which lumps of pumice stone may be placed for increased area) or by such dry H₂O absorbers as magnesium perchlorate. The CO₂ is absorbed by alkali, such

as a concentrated solution of NaOH or $\text{Ba}(\text{OH})_2$, or more conveniently by "shell caustic". Soda lime is less convenient.

Fig. 12.13a—A closed circuit apparatus for measuring the O_2 consumption by the spirometer method.

Fig. 12.13b—A closed circuit apparatus for measuring the O_2 consumption by the spirometer method.

Air is drawn through the chamber and absorbers by some pump, such as a water pump, P . It is convenient to keep a record of the rate of air passage by some meter, M .

The air is freed from its CO_2 and H_2O by absorbers 1 and 2, respec-

tively, before it enters the chamber, *Ch*; the air leaving the chamber deposits its H_2O and CO_2 in absorbers 3 and (4 + 5) respectively. Thus some atmospheric O_2 is retained by the system (in the form of CO_2), but nothing leaves the system. Hence, while the *animal loses weight* during the trial (it loses H_2O and CO_2), the *system as a whole* (that is chamber and absorbers 3, 4, 5) *gains weight*; the gain represents O_2 consumed. So, we have H_2O vaporized (absorber 3); CO_2 produced (absorbers 4 and 5); and O_2 consumed (gain in the system *as a whole*).

Fig. 12.14—The original Haldane chamber open-circuit gravimetric method.

Fig. 12.15—A modification of Haldane apparatus employed for measuring the metabolism of rabbits and chickens.

The numerical computation is a bit involved; it is therefore discussed in detail.

Numerically, the O_2 consumption is the difference between the H_2O and CO_2 gain in absorbers 3, 4, and 5 on one hand and loss in weight of the animal and chamber on the other. Thus

H_2O and CO_2 gain by absorbers 3, 4, and 5.....	5.32 g
Weight loss by animal and chamber.....	2.91 "
The O_2 consumed is, therefore.....	2.41 "

Fig. 12.16—A Haldane metabolism apparatus we used for rats. Number 5 is the chamber (a No. 5 Kerr Mason jar resting on a light tin platform). The train preceding #5 frees the incoming air from H_2O , CO_2 ; the train following #5 absorbs the H_2O , CO_2 liberated by the rat. The increase in weight of trains 5 to 10 inclusive represents O_2 consumed; 6 to 7, H_2O vaporized; 9 to 10, CO_2 exhaled.

Fig. 12.17a—The four-chamber Haldane apparatus now employed by us for measuring the metabolism of rats in a constant-temperature cabinet. To avoid confusion, only one chamber is shown in the cabinet. For photographs see Figs. 12.17b and c.

12.2.4: Open-circuit chamber method for larger animals involving gas analysis. This method, devised by Pettenkofer²⁶ (1862), is similar to the Haldane in general design, but as the chamber is too large for weighing and the CO₂ production is too much for absorption, air-flow metering, aliquoting, and gas analysis are employed.

The air coming into the chamber is assumed to contain²⁷ 0.031 per cent CO₂ and 20.939 per cent O₂; the outgoing air is analyzed for its CO₂ and O₂ content. The rate of air circulation is measured. The percentages of O₂ decrement and CO₂ increment in the outgoing air are computed; the products of these and the ventilation rate is the rate of O₂ consumption and CO₂ production.

This chamber method is illustrated in Figs. 12.25 (Benedict and Ritzman²⁸), 12.24 (Grafe²⁹), 12.26 (Benedict-Ritzman type used by us for a while). It is also used by Möllgaard, Lefèvre³⁰, Kleiber³¹, Mitchell³², and in the Pennsylvania respiration-calorimeter³³.

The measurement of the ventilation rate may be done with large commercial gas meters. The aliquoting is a complex matter (see Figs. 12.24 after Grafe, 12.25 and 12.26 after Benedict and Ritzman; and especially the papers cited).

The most time-consuming aspect of the operation is the gas analysis of chamber air, which is outdoor air slightly (about 1 per cent) contaminated with expired air; and a slight error in the analysis of this dilute air is greatly magnified in the computed heat production. The difficulty is increased if the expired air contains combustible gases, as it does in ruminant-exhaled air. We used the Benedict-Ritzman chamber (Figs. 12.25 and 12.26) for a year or two, but discarded it because of the expense for gas analysis, computing, etc., and adopted in its place the closed-circuit volumetric mask method, previously described (Sect. 12.2.1), and also the open-circuit mask method described below.

12.2.5: Open-circuit mask method for larger animals involving gas analysis.

This method has been long used for measuring human metabolism;³⁴ it in-

volves collection of all the expired air into a Douglas³⁵ bag (Fig. 12.19a) or into a Tissot spirometer³⁶ (Fig. 12.19b) over a short period. The analysis of directly expired air, containing several per cent CO₂ increment and O₂ decrement, is very much simpler than that of chamber air containing a fraction of a per cent of CO₂. The analysis of the chamber air has to be at least ten times as precise (to 0.002 per cent) as of directly expired air (0.02 to

The following paragraphs describe the apparatus especially for analysis of exhaled air from cattle involving analysis for CH_4 .

The Haldane gas-analysis apparatus (Fig. 12.20) is composed of a 10-cc burette in which the gas sample is confined. This burette is connected to a leveling bulb where-with the gas sample can be drawn in or forced out, and to two 30-cc absorbers, one for CO_2 and one for O_2 . The burette is also connected to a combustion pipette for oxidizing the CH_4 to CO_2 . The CO_2 absorber contains a 20 per cent solution of KOH ; the O_2 absorber contains a solution made by dissolving 10 g pyrogalllic acid⁴⁹ in 100 cc saturated

Fig. 12.20b—Haldane gas-analysis apparatus.

solution of KOH (Sp. gr. 1.55). Temperature, barometric pressure, and water-vapor changes are adjusted by a compensating tube of the same size and shape as the gas burette. Both burettes are kept in a water bath. Some distilled water is kept in the compensating burette. The potash-absorption pipette connects the air between the control and sample tubes. The CH_4 is burned by heating the platinum wire in the combustion pipette to white heat (from a 4-volt current). The resulting CO_2 is measured by absorption in the KOH burette, and CH_4 computed from the equation:

From the above equation, 1 volume (or 1 mol) CH_4 produces 1 volume CO_2 , so that the

⁴⁹ Other O_2 absorbents may be used, as stick phosphorus, or alkaline $\text{Na}_2\text{S}_2\text{O}_4$ solution.

CH₄ per cent is the percentage ratio of the volume CO₂ formed in combustion divided by the total gas sample; or in equation form,

$$\% \text{ CH}_4 = \frac{\text{vol. CO}_2 \text{ formed in combustion}}{\text{total volume of gas sample}} \times 100 \quad (12.2)$$

$$= \frac{\text{vol. shrinkage due to combustion}}{2(\text{total volume of gas sample})} \quad (12.3)$$

$$= \frac{\text{vol. shrinkage due to combustion} + \text{vol. CO}_2 \text{ formed in combustion}}{3(\text{total volume of gas sample})} \quad (12.4)$$

Equation (12.2) follows from the fact, shown in equation (12.1), that, discounting the H₂O which condenses, 1 volume CH₄ produces 1 volume CO₂; equation (12.3) follows from the fact, shown by equation (12.1), that the volume of CH₄ present is $\frac{1}{2}$ the contraction on combustion; equation (12.4) follows from the fact, shown by equation (12.1), that when the CO₂ has been absorbed, there is a diminution of $\frac{1}{3}$ of the volume.

Equation (12.1) also shows that twice as much O₂ as CH₄ disappears in the combustion of CH₄.

In the following computation, it is assumed that the inspired air is pure outdoor air which contains 0.031 per cent CO₂, 20.93 per cent O₂ and 79.04 per cent N₂, and that no change occurs in the volume of N.

The following computations illustrate the methods and results.

Analysis of barn-yard air (1-16-38)

Volume of air taken into burette.....	9.663 cc
Volume after CO ₂ absorbed.....	9.659 cc
CO ₂ absorbed*.....	.004 cc
% CO ₂04*
Volume after O ₂ absorbed.....	7.633 cc
O ₂ absorbed.....	2.026 cc
% O ₂	20.97*
% N ₂ = 100 - (.04 + 21.04) =.....	78.92*

* It is usually assumed that pure outdoor air contains 0.031 per cent CO₂, 20.94 per cent O₂ and 79.03 per cent N. It is very important to have appreciable amounts of acidulated water in the burette, or the burette becomes alkaline and stores CO₂, with resulting apparently low CO₂ values.

Analysis of directly expired air (by mask, valves, gas meters) for CO₂, CH₄, O₂ and computation of R.Q., and heat production.

Volume after combustion of CH ₄ and absorption of resulting CO ₂	9.648 cc
CH ₄ produced = $\frac{1}{4}$ (9.727 - 9.648) [see eq. (12.4)].....	0.026 cc
% CH ₄ in expired air.....	0.26
Volume after O ₂ absorbed.....	7.858 cc
O ₂ absorbed = 9.648 - 7.858 =	1.790 cc
Total O ₂ absorbed, including that used for oxidation of CH ₄ = 1.79 + 2 × 0.026 =	1.842 cc
[see eq. (12.1) indicating twice as much O ₂ absorption as CH ₄ oxidation]	
O ₂ in expired air.....	18.41 %
N ₂ in expired air = 100 - (2.77 + 0.26 + 18.41) =	78.56 %

To compute the volume of O₂ retained by the animal, the volume of O₂ expired is deducted from the volume of O₂ inspired.

The total volume of expired air for the 30-minute period, as measured by gas meters and corrected to standard conditions of temperature and pressure, is 2043.4 liters.

The percentage of N₂ in this sample of expired air is 78.56 per cent, as compared to 79.03 per cent, the known percentage in outdoor air. Since N₂ is not retained by the animal, the same volume (STP) of N₂ is expired as is inspired. The decrease in the percentage of N₂ expired over that inspired means that the total volume of air expired was different (more in this case) from the total volume inspired. The reason for the change in volume in the air, on passage through the lungs, is that the R.Q. is *not* equal to 1.

The air inspired during the 30-minute period must have had such volume that the N₂ percentage was 79.03 per cent instead of 78.56 per cent, the percentage found in expired air. The volume of inspired air may (having 79.03 per cent N₂) be computed by the inverse proportion:

$$\text{Vol. inspired air:Vol. expired air::78.56:79.03}$$

$$\text{Therefore volume of inspired air} = \frac{78.56}{79.03} \times 2043.4 = 2031.2 \text{ liters}^{42}.$$

The content of outdoor air is 20.94 per cent. Therefore

$$\text{Volume O}_2 \text{ in outside air inspired (STP)} = 2031.2 \times .2094 = 425.33 \text{ lit}$$

$$\text{Volume O}_2 \text{ in expired air (STP)} = 2043.4 \times .1841 = \frac{375.19}{49.14} "$$

$$\text{Volume O}_2 \text{ consumed by animal} = \frac{375.19}{49.14} "$$

The O₂ consumed expressed as a percentage of expired air is then:

$$\frac{49.14}{2043.4} \times 100 = 2.40\%$$

The excess of CO₂ expired over CO₂ inspired can be computed in the same manner. The CO₂ in outdoor air is approximately 0.03 per cent.

$$\text{Volume CO}_2 \text{ in expired air} = 2043.4 \times .0277 = 56.60 \text{ lit}$$

$$\text{Volume CO}_2 \text{ in inspired air} = 2031.2 \times .0003 = 0.60 "$$

$$\text{CO}_2 \text{ increment} = 56.00 "$$

$$\text{CO}_2 \text{ increment as a percentage of expired air} = \frac{56}{2043.4} \times 100 = 2.74\%$$

⁴² Table 11, "Volumes of oxygen in incoming air corresponding to 100 volumes of outgoing air with different percentages of nitrogen. 79.03:%N₂ = 20.94:X", in Carpenter's Tables⁴¹ will be helpful in these computations.

The correction due to volume change is so small that it may be neglected and the percentage CO_2 increment may be obtained by subtraction prior to correction thus:

$$\% \text{CO}_2 \text{ increment} = 2.77\% \text{ in expired air } 0.03\% \text{ in inspired air} = 2.74\%$$

$$\text{R.Q.} = \frac{\text{CO}_2 \text{ increment}}{\text{O}_2 \text{ retained}} = \frac{2.74}{2.40} = 1.14$$

The heat production is the volume of expired air \times % O_2 decrement times thermal equivalent of the O_2 at the given R.Q. = $2043.4 \times .024 \times 5.047 = 247.5$ Cal in 30 minutes, or 11,880 Cal/day.

We next proceed to illustrate another analysis on the same cow 428 after she had fasted for two days, with a consequent decrease in R.Q. from over 1 to near 0.8, so the N_2 per cent is increased on passing through the pulmonary system, because less CO_2 is produced than O_2 is consumed.

II. Cow 428 after 2 days' fast

Volume of air passed through gas meter in 30 minutes.....	1330.5 lit
Average meter temperature.....	32.8° C
Barometric pressure.....	743.6 mm
STP correction factor.....	0.830
Expired air as at STP, 1330.5×0.830	1104.3 lit/30 min
Vol. expired air sample in gas burette.....	9.670 cc
Vol. after CO_2 absorbed.....	9.490 cc
CO_2 absorbed.....	0.180 cc
% CO_2 in exhaled air.....	1.86
Volume after combustion of CH_4 and absorption of resulting CO_2	9.481 cc
CH_4 produced = $\frac{1}{2} (9.490 - 9.481)$	0.003 cc
% CH_4 in expired air.....	0.03
Volume after O_2 absorbed.....	7.779 cc
O_2 absorbed ($9.481 - 7.779$).....	1.802 cc
Total O_2 absorbed in alkali, including that used for CH_4 oxidation, $1.802 + 2 \times 0.003 =$	1.808 cc
O_2 in expired air.....	18.70 %
N_2 in expired air = $100 - (1.86 + 18.70 + 0.03) =$	79.41 %
O_2 consumed $20.94 - 18.70 =$	2.24 %

$$\text{Apparent R.Q.} = \frac{1.86 - .03}{2.24} = \frac{1.83}{2.24} = 0.821$$

The R.Q. corrected for volume changes may be computed by an analogous but shorter method than that previously explained, as follows:

$$\begin{aligned} \text{R.Q. corrected for changes in } \text{N}_2\% : \text{corrected } \text{O}_2 \text{ in inspired air} = \\ 20.94 \times \frac{79.41}{79.03} = 21.04 \end{aligned}$$

$$\begin{aligned} \text{"True" R.Q., that is, R.Q. corrected for volume changes} = \\ \frac{1.86 - 0.03}{21.04 - 18.70} = \frac{1.83}{2.34} = 0.78 \end{aligned}$$

$$\begin{aligned} \text{Heat production} &= 1104.3 \times 0.0234 \times 4.776 \\ &= 123.4 \text{ Cal in 30 minutes} \\ &= 5923 \text{ Cal/day} \end{aligned}$$

12.2.7: Electric methods of gas analysis. The Haldane method of gas analysis, and especially its modification for analysis of chamber air such as

Carpenter's, is exacting and time-consuming. The electrometric method here discussed is simple and rapid in operation, but difficult in adaptation and calibration.

The history, principles, and application of the method may be obtained from Palmer and Weaver's monograph⁴³. This method is based on (1) differences in thermal conductivity of different gases, and (2) differences in electrical resistance of wires at different temperatures, with the result that (3) if the wire has a high temperature coefficient of electrical resistance, this resistance will have a value corresponding to the thermal conductivity; therefore this resistance will have a value corresponding to the composition of the gas surrounding the wire.

This method then consists in comparing the resistance of two electrically heated wires, surrounded respectively by the gas under investigation, and by a standard or reference gas. The resistance of the two wires is compared by galvanometer, voltmeter, or potentiometer. The readings are calibrated empirically in terms of percentage composition of the gas under investigation under the given conditions.

The greater the difference in conductivity between the components of the gas under investigation the greater the precision of the measurement. The following arbitrary values (ratio of the product of potential difference and current of given gas to that of air when the resistance is 5.66 ohms, wire temperature 100° C, and temperature of chamber wall surrounding the wires 30° C) indicate the relative power losses in various gases: air, 1.000; CO₂, 0.697; N₂, 0.991; O₂, 1.024; SO₂, 0.440; H₂, 6.613. Because N₂ and O₂ and air have nearly the same thermal conductivity, this method is not sensitive for evaluating the O₂ per cent in air. But it is suitable for evaluation of CO₂ because the thermal conductivity of CO₂ differs considerably from that of air. These differences are illustrated in Fig. 12.21. This method is rapid, the results may be recorded automatically in the absence of an operator, and the readings are independent of atmospheric pressure. It has been used successfully for CO₂ determination in alveolar air ("alveolar air indicator" or "Katharometer")⁴⁴ and also in normally expired air⁴⁵.

The "Katharometer"⁴⁶ measures the resistance in an unbalanced wheatstone bridge by the deflection of the needle of a millivoltmeter. In other commercial instruments⁴⁷, the resistance in a wheatstone bridge is balanced by using a slide wire to bring a galvanometer to zero deflection.

Carpenter⁴⁸ described a modification of Noyons' "diaferometer thermique"⁴⁹ for analysis of both CO₂ and O₂. The measurements are based on the deflections of a sensitive galvanometer which indicates changes in resistance of platinum wires caused by differences in the cooling power of the gases surrounding the wires. It is not recommended for use in the presence of CH₄, H₂, or CO. This apparatus, like the others, has to be checked by the chemical method of gas analysis.

12.3: Food calorimetry. The gross energy value of a feed or food may be determined either by (1) *direct calorimetry*, by burning a sample in a water-jacketed chamber and measuring the rise in the water temperature, or (2) *indirect calorimetry*, by burning the sample in a "respiration" apparatus having a combustion chamber instead of a pulmonary system of an animal, and measuring the O_2 consumed, and/or CO_2 produced, and then computing the heat production from the thermal values of the O_2 for the given R.Q. (Table 12.1).

The direct method, devised by Berthelot, is the more commonly used⁵⁰. It is called a bomb calorimeter because the weighed sample is placed in a heavy steel "bomb" charged with O_2 under pressure (at least 20 atmospheres). The energy content of the sample is computed from the temperature rise

Fig. 12.21—Katharometer calibration chart, for electrometric (thermal conductivity) analysis of expired air.

of the surrounding water, weight of the water, heat capacity of the apparatus, and related corrections.

Benedict⁵¹ devised an indirect method similar in principle to the Benedict clinical metabolism apparatus. It consists (Fig. 12.22) of (1) a combustion chamber, *A*, (corresponding to the pulmonary system in the Benedict-Collins clinical metabolism apparatus) in which the sample is burned; (2) soda lime, *B*, for absorbing the CO_2 ; (3) air-tight motor blower; and (4) spirometer, *P*. The energy content of the sample is computed from the O_2 used for the combustion, and from the thermal values of O_2 as given by Benedict (determined with the aid of the bomb calorimeter).

12.4: Historic comments. As noted in the introductory quotation, Lavoisier is the founder of biocalorimetry. It was not, however, until about 1850 that this work was taken up again with the appearance of the Regnault and Reiset practical biocalorimetric methods (Fig. 12.10).

An interesting modification of this closed-circuit apparatus is the *methode de confinement*⁵² or the *pneumatische Kammer*⁵³. The animal is kept in a closed chamber under constant volume, for example, in a desiccator or under constant pressure, as under a floating bell (Fig. 12.23), and the confined air is analyzed, at the end of a convenient period, for the CO₂ increment and O₂ decrement. According to Lulanie, the CO₂ may be increased to 6 per cent and the O₂ decreased to 11 per cent. Two per cent CO₂ in the atmosphere does not affect metabolism in man⁵⁴.

Giaja⁵⁵ employed "confinement-method" chambers for animals ranging from mice to men. There are too many types of closed-circuit apparatus for man⁵⁶ and laboratory animals⁵⁷ to be described here.

Fig. 12.22—Benedict's oxycalorimeter.

As previously noted, the first modern open-circuit metabolism apparatus was built in 1862 by Pettenkofer and Voit, and the first direct calorimeter, combined with the Pettenkofer open circuit apparatus, in 1894 by Max Rubner.

Following Rubner's completion of the calorimeter for dogs in 1891, Atwater (the first director of the first Federal American experiment station, established in Middletown, Connecticut, in 1875, and the first director, 1888, of the U. S. Office of Experiment Stations) and Rosa (chief physicist of United States Bureau of Standards) began work in this country on a

calorimeter for man in 1892, completing it in 1897. With it, Atwater⁵⁸ and associates extended Rubner's findings concerning the agreement between observed and computed values for heat production to include man.

The Atwater-Rosa respiration calorimeter measured the CO₂ production but not the O₂ consumption. The later feature (closed circuit) was developed by Benedict in the Atwater-Benedict respiration calorimeter,⁵⁹ thus making it possible to measure the R.Q.

Lusk and associates⁶⁰ built two respiration calorimeters, a small one for dogs at the Cornell Medical College and a large one for man at the Bellevue Hospital (now at the New York Medical Center). The later calorimeter, directed by Du Bois from its beginning, is at the time of this writing used for investigating mechanisms of heat loss in the human body.

Fig. 12.23—Confinement method for measuring the respiratory exchange (Courtesy Marie Steuber).

It is instructive to note that Rubner (1854–1932), Atwater (1844–1907), and Lusk (1866–1932) were pupils of Carl Voit (1831–1908); that Armsby (1853–1921) was for a time at the Mockern Agricultural Experiment Station under Voit's influence, but directed by Kuhn, Kellner, and Fingerling. Voit was a pupil of Liebig (1803–1873), who had studied under Gay-Lussac (1778–1850), who was in turn a pupil of Berthelot (1748–1822) and Laplace (1749–1827). The latter was a collaborator of Lavoisier (1743–1794).

Armsby⁶¹, the most influential American investigator in farm-animal nutrition, adopted the Atwater-Rosa respiration calorimeter for cattle, with funds provided (1898) by the U. S. Department of Agriculture. The use of this calorimeter began in 1901. It is the only available respiration calorimeter for cattle.

Armsby's calorimetric contributions revolved about the evaluation of the energy value of feeds for relatively mature cattle. His first work was concerned with testing on ruminants the validity of Rubner's theory (1883) to the effect that carbohydrates, fats, and proteins may replace each other in proportion to their metabolizable energy when fed in submaintenance amounts. These ideas were modified by Rubner's later formulations of the conception of specific dynamic action. Armsby has shown that the specific dynamic action of feeds is greater for ruminants than for man, and that the processes of digestion and assimilation (heat increment of feeding) should be taken into account in the determination of the energy values of feeds. He found (1908) that only 45 per cent of the energy from hay is utilized; the remainder is wasted: 41 per cent in feces, 6.8 per cent in methane, 7.3 per cent in urine. These considerations led Armsby to the concept of net energy values of feeds (Chs. 2 and 5).

Fig. 12.24—Grafe's open-circuit chamber for measuring the respiratory exchange in large animals.

Other direct calorimeters for farm animals are Deighton's on pigs⁶² and on fowl⁶³ and Barott's⁶⁴ on chick embryos and chickens. The respiration calorimeter of Lefèvre and Auguet³⁰ has been used for man and for sheep.

12.5: Summary and general comments. Biocalorimetric methods are divided into (1) *direct*, involving the measurement of heat dissipation; (2) *indirect*, involving the measurement of heat production from the rates of O₂ consumption and CO₂ production; (3) *mixed*, such as the *partitional calorimetry* (involving the measurement of heat loss by radiation, conduction-convection, and vaporization, and *insensible-perspiration calorimetry* (involving

accurate measuring of weight loss of the animal due mostly to water vaporization), both discussed in Chapter 11; (4) *combined*, including both the direct and indirect methods, as in the Pennsylvania respiration calorimeter.

The direct methods may be of the water-cooling or of the compensation type (involving the balancing of heat produced by the animal in one chamber,

Fig. 12.25—The Benedict-Ritzman open-circuit method for measuring the respiratory exchange in large animals.

and by heat produced through measured amounts of electrical energy in the same or another chamber of the same size). The indirect methods may be of the closed-circuit type (involving the rebreathing of air, usually with removal of the CO_2 by circulation through purifiers and addition of fresh O_2), or of the open-circuit type (involving the metering and analyzing of the expired air).

From the standpoint of scientific interpretability of results, method (4), respiration calorimetry is best. Unfortunately, this method is apparently not practicable for farm animals except for one well-equipped institution in the country; and even in this case the gathering of data is too laborious and slow, to satisfy desires for "practical results" in "reasonable time", and the data are insufficient for statistical analysis.

But even the indirect method (open-circuit respiration-chamber gas analysis) as employed in five laboratories (in U. S., Benedict-Ritzman, Mitchell-Hamilton, Kleiber; in Europe, Möllgaard, Fingerling, Popov-Thome) is too expensive and too slow, and the data obtained are usually not sufficient for statistical analysis. We have therefore adopted for cattle and other farm animals the mask method, similar to those used for measuring basal metabolism in humans, for both closed- and open-circuit work.

The measurement of O_2 consumption alone (closed-circuit spirometer method) is quite sufficient for "normal" animals within the R.Q. limits of 0.71 and 1.0. Within these R.Q. limits the caloric equivalent of O_2 is well known and relatively constant. The caloric value of O_2 may perhaps be constant even above the R.Q. value of 1.0, as pointed out by Benedict⁶⁵, who, however, was criticized⁶⁶ for this conclusion, and especially for the suggestion that direct calorimetry is unnecessary. There is no doubt that the indirect method is not rigorously sufficient, as when oxygen is used in the body for purposes other than oxidation, such as massive conversion of carbohydrate containing some 53 per cent O_2 to fat containing 11 to 12 per cent, with corresponding apparent depression of O_2 consumption (or raising of the R.Q.). Many agricultural processes consist in such transformation of dietary carbohydrate to body fat⁶⁷, milk fat⁶⁸, and egg fat.

Then, too, many of the metabolites are not members of the three standard nutrients, carbohydrate, fat, and protein⁶⁹; nor do these substances react according to type, either because of dietary condition⁷⁰ or metabolic abnormalities, as in diabetes, with formation of sugar from protein and other sub-

Bulls. 55, 61, 73, and others. Benedict,⁶⁵ (1937). (R.Q. 1.47 for fattening geese.) Wierzuchowski, M., and Ling, S. M., *J. Biol. Chem.*, **64**, 697 (1925) (R.Q. 1.58 for fattening hogs). Rapport, D., *et al.*, *J. Biol. Chem.*, **60**, 583 (1924), who quotes M. Bleibtrau [*Pflüger's Arch.*, **85**, (1901)], obtaining R.Q. 1.38, and Bleibtrau's correction equation for conversion of C.H. to fat:

$$270.06 \text{ g glucose} \rightarrow 100 \text{ g fat} + 54.61 \text{ g H}_2\text{O} + 115.45 \text{ g CO}_2$$

In this transformation of carbohydrate to fat, it is assumed that 60.7 Cal, or 6 per cent of the energy of carbohydrates is lost. The heat of combustion of fat was assumed to be 9.50 Cal/g, and of glucose 3.743 Cal/g. The suggestion is made to multiply the excess CO_2 liters above the R.Q. of 1 by 0.8 Cal and add the product to the calculated heat value of the protein and C.H. which are being oxidized. A liter of CO_2 above the non-protein R.Q. of 1.0 is supposed to correspond to deposition 1.7 g fat derived from 4.80 g glucose, or from 5.06 g starch. See also Talbot, F. S., *et al.*, *Am. J. Physiol.*, **124**, 246 (1938).

stances, which results in an abnormally low R.Q., or perhaps even in formation of sugar from fat, as in hibernation, shown by an abnormally low R.Q.

Some synthetic reactions may even be endothermic (Chs. 2 and 3); others may be anaerobic when O_2 consumption is not related to heat production. We have the massive heat production of fermentation in the digestive tract, especially of ruminants, which is unrelated to respiratory metabolism or at any rate to O_2 consumption. Catabolism of protein may occur in various ways, oxidative and non-oxidative (Chs. 2, 4). There may be, after all, a great need for more direct calorimetry in combination with indirect, especially for farm animals. In the meantime we do what we can.

Other indirect calorimetric methods might be cited. Thus, if the body weight remains constant over a long period and its composition also remains constant, the heat production may be estimated from the physiological-fuel value of the consumed food. This method is frequently used for estimating energy expenditures and dietary-energy needs in humans.⁷¹

Fig. 12.26—Photograph (by T. M. Carpenter) of the Benedict-Collins open-circuit chamber for measuring metabolism used in our laboratory (Missouri).

The following example for measuring heat production by difference⁷² (on rats) seems to be satisfactory.

Energy of feed consumed.....	2275.6 Cal
“ “ feces.....	171.6 “
“ “ urine*.....	75.6 “
“ “ fat stored.....	101.0 “
“ “ protein stored.....	88.9 “
Heat production by difference.....	1838.6 “

* 2.1 Cal. were added to the energy of the urine as representing the energy loss during drying (g N loss \times 5.447).

Then there are several relations of heat production to various physiological functions, such as ventilation rate, respiration rate, pulse rate (Ch. 24) and the curious one relating

Chapter 13

Basal Energy and Protein Metabolism in Relation to Body Weight in Mature Animals of Different Species

I do not know where or when the various species of animals were given their basal metabolism. Perhaps Noah did it when they left the Ark. I suppose that the reason he could not do a uniform job with the animals was because he did not have scales small enough for the dwarf mice and large enough for the bull and the elephant. *E. F. Du Bois*

13.1: Definitions. *Basal energy metabolism*, also called *post-absorptive metabolism* and *standard metabolism*, is the heat production during complete rest in a thermoneutral environment (Ch. 11) in post-absorptive condition (Ch. 4); it is the resting energy metabolism in a thermoneutral environment uncomplicated by the heat increment of feeding.

As previously explained (Ch. 3), it is doubtful whether much over 25 per cent of the basal metabolism is expended for the work of circulation, respiration, secretion, excretion, and muscle tonus. The work of blood circulation under basal conditions is estimated to account for from 5 to 15 per cent of the total basal metabolism energy; that of the kidney 5 per cent; and that of respiration from 5 to 15 per cent. The remaining basal metabolism energy represents the cost of maintaining the thermodynamically unstable and improbable living state and free-energy losses incidental to the purposeless enzyme activities (analogous to yeast enzymes which continue their catalytic activities after the death of the yeast), and maintaining the characteristic body temperature.

Basal-energy metabolism is a convenient baseline for measuring various energy increments, such as heat increments of muscular work, of feeding, of lactation, of gestation, of keeping warm in cold weather, and the like.

We shall also use the term *resting-energy metabolism* which differs from basal only in that the animal is not in post-absorptive condition.

Endogenous nitrogen excretion is the lowest level of nitrogen excretion attained after an empirically defined time interval (about four days in rat and man) on a low nitrogen but otherwise complete and abundant diet. Endogenous nitrogen excretion, like basal metabolism, is a convenient base for measuring various nitrogen-excretion increments, such as those due to food ingestion.

We shall be concerned mostly with the urinary endogenous nitrogen because of the difficulty of measuring the fecal endogenous nitrogen excretion. The fecal nitrogen is made up of three parts: (1) endogenous or metabolic N, derived from the body; (2) alimentary-lining N, derived from the alimentary lining as a result of "handling" the food; (3) undigested food N. The amount of endogenous fecal nitrogen is profoundly influenced by the dietary roughage and protein. "Protein in direct contact with the mucosa is one of the best stimulants to gastric and intestinal secretions, the residues from which constitute the bulk of 'normal' feces"¹.

Folin² demonstrated the presence of two kinds of urinary nitrogen, endogenous and exogenous, in a classic series of papers published in 1905. "I would call the protein metabolism which tends to be constant, *endogenous* metabolism, and the other, the variable protein metabolism, I would call the *exogenous* metabolism". Because of the constancy of the endogenous metabolism he assumed that it represents "an essential part of the activity which distinguishes living cells from dead ones".

Folin demonstrated that the principal end product of the dietary protein disintegration is urea, and the greater the amount of nitrogenous food ingested above the needs, the larger the amount of urea and ammonium salts excreted. The end product of endogenous metabolism apparently least affected by protein ingestion is creatinine. But neutral sulfur and to a less extent uric acid also represent body or endogenous protein metabolism. Urea and creatinine excretion levels, then, represent extremes in the extent to which they are influenced by dietary protein.

Employing isotopic nitrogen to label the amino acids under investigation in metabolism, Schoenheimer³ found extensive interchange of nitrogen between dietary amino acids and tissue protein, and concluded that "it is scarcely possible to reconcile our findings with any theory which requires a distinction between these two types of nitrogen", referring to endogenous and exogenous nitrogen. However, Burroughs and Mitchell⁴ presented evidence substantiating the independence of endogenous and exogenous types of nitrogen metabolism, and attributed the observation of Schoenheimer to the rapid interchange, not in *tissue protein* but in the labile or fluid "deposit protein", which is assumed to rise and fall with the rise and fall of dietary protein.

There are serious difficulties in evaluating endogenous urinary nitrogen because its output varies⁵ with (1) duration on N-free diet period prior to commencement of taking the data for evaluation of endogenous N (Fig. 13.19); (2) nature and amount of food intake prior to the experiment; (3) amount of indigestible material in the diet⁶.

The endogenous N excretion is evaluated by feeding animals for a given period on practically N-free but otherwise complete diets, or preferably, according to Mitchell⁷, on an otherwise nitrogen-free diet containing 4 per cent of whole egg protein.

The apparent endogenous nitrogen level is especially dependent on the length of time the animal is fed on the nitrogen-low diet, and on the nature of this diet. The first effect

of such a diet is to depress the food consumption, which upsets the entire nutritional balance. The basic principle of the method is that the animal should consume plentifully a diet which should be complete in every respect, except that it is low in nitrogen.

This chapter is concerned with the relation of basal energy metabolism and urinary endogenous nitrogen excretion to body weight in *mature animals of different species* ranging from mice to elephants, with special reference to farm animals. Chapter 14 is concerned with similar relation in *growing animals of the same species*, and Chapter 15 with the total maintenance cost in relation to body weight.

13.2: Basal metabolism and the "surface law". A most intriguing observation in basal metabolism studies is that the basal heat production *per unit body weight* in homeotherms decreases rapidly with increasing weight. Thus the basal metabolism *per unit weight* of such small animals as mice and canaries is 20 to 25 times as great as of large animals, such as cattle. This means that the basal-metabolic significance of a physical weight unit in a canary is about 25 times that in a cow. This means that simple body weight is not a suitable reference base for metabolism. The purpose of this section is to discuss critically the reference-base problem in relation to basal energy and protein metabolism. This discussion is based largely on the data in Tables 13.1 and 13.2 (at the end of this chapter), rearranged respectively from our work⁸ and Benedict's⁹.

According to the laws of Newton and Stefan-Boltzmann (Ch. 11), the rate of cooling of a body is proportional to its surface area. Now if the heat loss is proportional to the surfaces, the heat production must likewise be proportional to the surfaces, since in homeotherms heat production must equal heat loss. Homeotherms must, therefore, have developed in the course of evolution a heat-production control to function in proportion to surface area. This, in brief, is the evolutionary logic of the "surface law".

This relation of heat production to linear size and to surface area was first formulated over a century ago by Rameaux and Sarrus¹⁰. To avoid reviewing many subsequent papers, it seems best to quote, in free translation, somewhat rearranged, this first formulation of the "surface law".

(1) Assuming constancy of body temperature, there must be equality between heat loss and heat production.

¹⁰ Sarrus et Rameaux, *Bull. de l'acad. de Med.*, 2, 538 (1837-8); Rameaux and Sarrus, *Id.*, 3, (1838-1839). Robiquet and Thillaye, who are sometimes credited with its discovery, merely reported the papers by Rameaux and Sarrus. For a detailed review, see Le Breton, E., *Ann. Physiol. physicochim. biol.*, 2, 606 (1926).

(2) Assuming equality of other conditions, heat loss is proportional to "free" surface.

(3) Heat production is proportional to oxygen consumption or approximately to inspired air.

(4) Since heat loss and heat production are proportional to "free" surface, and since surfaces vary with the squares of the homologous sides, it follows that oxygen consumption, heat production, and heat loss are proportional to the square of the corresponding dimensions of the animals under comparison.

(5) This proportionality between oxygen consumption and free surface may be achieved in several ways, one of which is by varying the lung surface and number of respirations.

These authors also presented relations between pulse rate, pulse volume, and body size.

The more recent formulations of the "surface law"¹¹ do not appear to the present reviewer to offer improvements on the original formulation.

In equation form, one may say that surface, or heat loss, or heat production, or oxygen consumption, Y , is proportional to the square of the linear size, L :

$$Y \propto L^2 \quad (13.1A)$$

or to the $\frac{2}{3}$ power of volume, or to the $\frac{2}{3}$ power of weight, W (if the specific gravity is constant), as indicated by the equation¹²

$$Y = aW^{\frac{2}{3}} \quad (13.1B)$$

or in more general terms

$$Y = aX^b \quad (13.2)$$

We are especially interested (Ch. 24) in what Sarrus and Rameaux had to say concerning the interrelation between oxygen consumption, respiration rate, pulse rate, pulse volume, and body size which anticipate: Hoesslin (1888), Krogh (1916), Henderson (1923), Read (1924), Teissier (1928), and Kleiber (1932) concerning the interrelation of blood flow or oxygen transport (which is proportional to pulse rate and volume per heart beat) and heat production.

¹¹ See Lusk, G., "The science of nutrition," 1928, and Du Bois, E. F., "Basal metabolism in health and disease", 1936.

¹² Derivations of equation B from A:

Surface area, S , varies with the square of the linear size, L
 $S \propto L^2$

Volume or (what is virtually the same) weight, W , varies with the cube of linear size

$W \propto L^3$

or linear size is the cube root of weight

$L \propto W^{\frac{1}{3}}$

and surface area, S , is therefore, the $\frac{2}{3}$ power of weight

$S \propto L^2 \propto (W^{\frac{1}{3}})^2 \propto W^{\frac{2}{3}}$

On converting the proportionality to an equality, we have

$S = aW^{\frac{2}{3}}$ (13.1B)

Thus, according to Kleiber¹³, "the influence of body size on metabolism may reasonably be related to oxygen transport" and "if the volume per beat were exactly proportional to the body weight and the pulse rate were exactly proportional to the $\frac{1}{4}$ power of body weight, the intensity of blood flow would be proportional to the $\frac{3}{4}$ power of the body weight". Henderson's results demonstrated a direct proportionality between circulation rate and basal metabolism. An interrelation exists between metabolic rate and pulse rate, and it has been suggested that pulse rate be used for estimating metabolic rate.¹⁴ We are thus indebted to Sarrus and Rameaux not only for originating the "surface law", but also for analyses of the more basic physiologic factors interrelated with metabolism.

Some ten years after the publication of the brief reports by Rameaux and Sarrus, there appeared the widely quoted book by Bergmann¹⁵, who seemed to have formulated the law independently of the French investigators.

Bergmann discussed many problems of more than passing contemporary interest such as: influence of body size (and consequently heat loss and metabolic intensity) on geographic distribution of animals; relative insulating properties of the skin of large and small homeotherms (Bergmann first employed the terms *homeotherm* and *poikilotherm*); possible influence of greater food consumption (by increasing what we now call specific dynamic action) and greater muscular activity (energy cost of work) per unit body weight in small than in large animals, which may assist small homeotherms to maintain their body temperature in spite of greater surface area and consequent greater heat loss.

The development of the Pettenkofer calorimetric method (Ch. 12) and of the Meeh surface-area-measurement method¹⁶ enabled Rubner in Germany, and Richet in France, to substantiate the surface law experimentally. Rubner¹⁷ investigated the law on dogs, and Richet¹⁸ on rabbits.

That heat production must vary with surface area rather than weight at low temperatures if small animals are to survive may be illustrated by computations by Kleiber¹³, which show that if heat production per unit weight (rather than per unit surface area) were as small in a 60-gram animal as in a

600-kilogram animal, the small animal could not maintain its temperature in temperate zones without a 20-cm (8-in) insulating cover; small-animal life would be impossible in temperate or frigid zones.

The neatest theoretical derivation of the surface law is due to Teissier¹⁹, who deduced it from the principle of similitude by dimensional analysis. Derivations from the theory of similitude are geometric in the sense that the ratio of the diameter to the circumference of a circle is geometric and constant, regardless of the size of the circle (Ch. 12).

From the theory of similitude, surface area varies with the square of linear size, regardless of size, provided only that the large and small animals are similar in the way that large and small circles are similar. Likewise, power

Fig. 13.1a—The surface integrator. The roller A is mounted on an ordinary revolution counter. The crayon is held against the marker by the spring in E.

(energy metabolism) varies with the square of linear size regardless of size, provided that the animals are strictly similar and the environmental conditions are strictly homologous²⁰. Since both surface area and power are proportional to the square of linear size, or to the $\frac{2}{3}$ power of volume, they are proportional to each other. The surface law is thus arrived at independently of physiologic considerations.

Since strict biologic similitude between animals in space and time is impossible, strict agreement between observed facts on animals and deductions

²⁰ Homology of environment is obtained at rest in post-absorptive conditions in thermal neutrality, i.e., under "basal conditions".

by dimensional analysis are impossible—only approximations can be made. The magnitude of the surface area and heat production level are interrelated in their common connection with linear size (and other factors, depending on which units we agree to consider as primary and which secondary).

Fig. 13.1b—The surface integrator.

Fig. 13.1c—The surface integrator in action.

The fact that the external *surface area per unit weight* declines with increasing body weight (Fig. 13.2b) probably “explains”, from the evolutionary viewpoint—the observation that the *basal metabolism per unit weight* declines with increasing body weight—the fact that the *metabolism per unit weight* in

the canary, for example, is about 25 times that of the cow. In the course of evolution only such small animals survived in the colder regions as developed heat-production mechanisms which function in direct proportion to the external surface, in which the ratio of heat production to external surface area is approximately constant.

So much for the remote, or evolutionary, control of the metabolic rate in proportion to external surface rather than to body weight. But what are the

Fig. 13.2a—The surface area, A , is plotted against weight, W , on arithmetic and on logarithmically divided paper. The equation for the data is $A = 0.15 W^{.66}$ (A in square meters, W in kgs.). See also Fig. 13.2b.

direct mechanisms which control this relationship, which cause the small animal to metabolize at such a high level per unit weight?

The metabolic intensity is controlled by what Crile called “energy releasing” organs, namely nervous and endocrine systems, especially the brain, pituitary, adrenal, and thyroid glands. Now, it will be presently shown (Ch. 17) that as animals increase in size, the pull of gravity, of course, increases directly with body weight, whereas the strength of the supporting structures, such as of the legs, tend to increase with the $\frac{2}{3}$ power of body

weight (with the cross-section *areas* of the supporting structures). Hence, to retain stability, the supporting structures grow more rapidly than the visceral organs, or the visceral organs grow less rapidly than the body as a whole, approximately in proportion to surface area. In brief, the size of the metabolism-controlling organs tends to vary more nearly with surface than with body weight. Since surfaces tend to vary with the $\frac{2}{3}$ power of body

Fig. 13.2b—The surface area, A , is plotted against weight, W , on logarithmically divided paper giving a linear distribution of the data. The equation for the data is $A = 0.15W^{.66}$ (A in square meters, W in kgs.).

weight, with approximately $W^{\frac{1}{3}}$, the *metabolically effective* body size is not simple weight, $W^{1.0}$, but more nearly $W^{\frac{1}{3}}$.

13.3: Metabolically effective body size vs. surface area. Since simple weight, $W^{1.0}$, is not a good reference base for basal metabolism, and since metabolism tends to vary more nearly in proportion to surface area or to $W^{\frac{1}{3}}$, shall we then employ surface area or $W^{\frac{1}{3}}$ as reference base? No, for the following reasons:

(1) The surface area of a *living* animal is not constant and cannot be measured in such manner that the results can be checked by different in-

investigators. Surface-area measurements are not even reproducible on a *dead* animal. Thus, Fig. 13.3 shows a 60 per cent difference in surface area as measured by a similar method by two investigators on dead rats.

(2) Surface area as it relates to heat loss changes with environmental temperature not only by “rolling up” in cold weather and “spreading out” in hot weather, but also by developing heat-conserving and heat-dissipating devices

Fig. 13.3—There is a 60% difference in surface area of rats as estimated by Mitchell and by Diak, employing the same general method for estimating area.

(by varying the fur or feathers, subcutaneous fat, caliber of the blood vessels, and the like), thus changing the *effective* or “free” surface area.

(3) It is true that surface area varies with the $\frac{2}{3}$ power of weight, but only in geometrically similar bodies of constant specific gravity; and small and large, young and old, fat and thin, animals—especially of different species—are not geometrically similar and not of constant specific gravity.

(4) Representing metabolism as a function of external surface area would imply that surface area is the “cause” of the metabolic rate, whereas, as ex-

plained above and in other chapters (7, 11, 17), the immediate causative mechanism resides mostly in the neuro-endocrine system and not in the external surface area. Moreover, according to Lambert's "law" of heat radiation, heat loss is proportional not to simple surface but to the profile of the projected area (Sect. 11.5).

For these reasons it would be a gross oversimplification to accept the very vague "surface area" as reference base. The $\frac{2}{3}$ power of weight, $W^{\frac{2}{3}}$, is a more definite reference base than area; but as explained above, there is no geometric reason for assuming that the exponent is exactly $\frac{2}{3}$, since animals are not geometrically similar. It seems more rational, as a matter of principle, to take as reference base not $W^{\frac{2}{3}}$ but W^b the value of the exponent b being determined on the basis of actual data.

As regards actual surface measurements, the data on humans have been compiled by Boyd²¹, and on animals by us^{22,23}.

We measured the surface area of about 600 farm animals by the method²² illustrated in Figs. 13.1 and 2. It consists in passing a revolving cylinder, attached to a revolution counter, over the surface of the animal. The area is the product of the number of revolutions made by the roller and the area of the roller.

Figs. 13.2 a and b indicate how data on the first group²² of 96 dairy cattle, ranging in age from birth to maturity, appear when plotted in various ways on logarithmic and also on arithmetic coordinate paper. On the logarithmic paper, the data are distributed beautifully around the straight line, with an average error of only 1.9 per cent, indicating that area is a fractional power function of body weight, as represented by equations (13.2) and (13.3). The numerical value of the exponent is, however, not $\frac{2}{3}$ (*i.e.*, 0.67) but of the order of 0.57. The numerical values of the exponent b of the other animals²³ measured by the integrator method (Fig. 13.1) are shown in Table 13.9.

For comparative purposes we fitted equation (13.2) to human data²³. The value of the exponent b varied with the range of data employed. When the data range in age from birth to maturity, the value of b in equation (13.2) is of the order of 0.70 (Area = $0.10W^{0.70}$, weight in kg, area in sq meters). If, however, the data are limited to a narrow age range such as those obtained by Mrs. Bradfield²⁴ on college girls, the exponent is only 0.55 (Area = $0.176W^{0.546}$). In other words, form and specific gravity vary with size at *constant age* in a different manner than with changing age during growth.

A similar result was obtained on the relation between surface area and weight of dogs. We found²³ that the value of the exponent b in equation (13.2) is 0.70 for Stewart's dogs, ranging in weight from 0.14 to 4.0 kg; and only 0.37 for Lusk's mature dogs ranging in weight from 6 to 12 kg.

Du Bois²⁵ suggested that "a tall, thin man may have exactly the same weight as a short, fat man, yet have a much larger surface area", and that there is need to correct

²¹ Boyd, Edith, "The growth of the surface area of the human body", University of Minnesota Press, 1935. For E. F. Du Bois' classic contributions see, "Basal metabolism in health and disease".

for this difference by taking linear size into consideration. This is evident from geometric considerations. The difference in the value of b for humans and for dogs when including wide and narrow age ranges is of the same type as observed by Du Bois on short and tall men. Du Bois' method of including a linear measurement proved to be highly successful for human data and is now generally employed. However, our attempt to include one or several linear measurements for relating area to size of farm animals gave disappointing results.

Fig. 13.3 is a graphic argument against adopting surface area as reference base for metabolism. Three groups of rats were measured by the same method, but by different investigators. The curve labelled (1), fitted to the data by Mitchell and Carman²⁶ is 25 per cent above curve (2), fitted to data by Lee²⁷; and curve (2) of Lee is 30 per cent above curve (3), fitted to the data by Diak²⁸. No two sets of data agreed, and the average difference between two of the sets is 60 per cent.

The above consideration of the surface-area problem leads to the conclusion that while external surface area is a factor in conditioning heat production, it is not logical to employ it as reference base, first because it is difficult to measure with precision the physical (anatomic) surface area, and certainly not the "free" or physiologic surface area—at least of non-human species; and secondly, because the immediate metabolism control resides not in the external surface but in the neuroendocrine system. We have given much space to surface area because of its historic interest, and because its importance is likely to increase in the near future with the accumulation of data on the mechanism of heat dissipation.

In addition to surface area, "active mass" or "protoplasmic mass" has been suggested for use as reference base for metabolism. This suggestion originated with Voit²⁹, and extended by Benedict³⁰, Le Breton and Schaeffer³¹, and others. The basic idea is that increase in size during growth is associated with increase in the proportion of protoplasm (products of cell differentiation): the ratio nucleus volume/cytoplasm volume or nucleus/cell declines with increasing size during growth of the animal, and that the metabolic rate, as well as growth rate, is conditioned by this ratio.

While much has been written on the active-mass theory, it is practically useless because it is even more difficult to measure "active mass" than surface area in spite of the many published methods³².

An analysis of published data on purine and total nitrogen in the body in relation to body weight and to heat production yielded much less satisfactory—indeed, very erratic—results than the relation of heat production to surface area.

The foregoing discussions indicate that it is theoretically more logical and practically simpler to relate metabolism, not to surface area or to W^1 , or to "active mass", or "protoplasmic mass", but to the noncommittal *physiologically effective* body size represented symbolically by W^b , the value of the exponent b to be determined from actual data. The ratio of metabolism, Y , to

The relation between the value of b in equation (1) and the percentage increase in Y when X is doubled, that is increased by 100%. Thus when the value of b in equation (1) is 0.50, the relative increase in Y (that is $\frac{dY}{Y}$) is 0.50 times the relative increase in X (that is $\frac{dX}{X}$), or $dY/Y = 0.50 dX/X$. This value of b holds when the change in X is very small, namely dX . But when X (body weight) is doubled, that is increased by 100%, then the relation between b and the percentage change in Y is given by the above curve and table. Thus when $b = 0.50$, the percentage change in Y when X is increased 100% is not 50%, but only 41.4%.

Fig. 13.4—The relation between the value of b in the equation $Y = aX^b$ or $Y = aW^b$ and the percentage change in Y when X or W is doubled. Derivation of equation relating percentage change with the exponent b : Let $Y_1 = aX_1^b$, and $Y_2 = aX_2^b$; therefore the increase in Y expressed in per cent of Y_1 is $100 \frac{Y_2 - Y_1}{Y_1} = 100X \frac{aX_2^b - aX_1^b}{aX_1^b} = 100 \frac{X_2^b - X_1^b}{X_1^b} = 100 \left(\frac{X_2}{X_1} \right)^b - 100$. When X_2 is twice X_1 , $X_2 = 2X_1$, and percentage change is given by $100 \left(\frac{2X_1}{X_1} \right)^b - 100 = 100(2^b - 1)$.

metabolically effective body size, W^b , or to X^b , should be approximately constant, a .

$$\frac{Y}{W^b} = a; \text{ or } \frac{Y}{X^b} = a \quad (13.2)$$

13.4: Properties of equations $Y = aX^b$ and $Y = aX^bH^m$ relating surface area or metabolism to body size. A brief discussion of the mathematical significance of equation (13.2) above may be helpful at this time.

This equation is usually written in the form

$$Y = aX^b \quad (13.2)$$

in which Y is metabolism, surface area, or other given dependent variable, and X is body weight or other independent variable.

This equation is generally known as a parabola, or a logarithmic equation, since on taking logarithms we obtain the equation

$$\log Y = \log a + b \log X \quad (13.3)$$

which, incidentally, has the same *form* as the linear equation

$$Y = a + bX \quad (13.4)$$

In fitting the logarithmic equation, (13.3) to data, exactly the same method is used as in fitting the linear equation (13.4), except that in place of Y or X we deal with $\log Y$ and $\log X$.

Just as linear equation (13.4) is a straight line on arithmetic paper, so logarithmic equation (13.3) is a straight line on logarithmic paper. As linear equation (13.4) represents constant *absolute* increase in Y for constant *absolute* increase in X , so logarithmic equation (13.3) represents constant *percentage* increase in Y for constant *percentage* increase in X . This is the feature of logarithmic coordinate paper: deviations from the average are shown spatially in proportion not to *absolute* but to *percentage* deviation. Thus a 10-lb deviation on a 100-lb animal is shown on logarithmic paper by the same distance as a 100-lb deviation on a 1000-lb animal, because in both cases the *percentage* deviation is the same. For practical purposes it is more useful to have data or tables of constant *percentage* than of constant *absolute* accuracy. The linear equation (13.4) is fitted to data by the method of least squares, on the assumption that a given *absolute* deviation about the fitted line is equally important to animals of different weight; the logarithmic equation (13.3) is fitted to data on the assumption that a given *percentage* deviation about the fitted line is equally important to animals of different size. It is obviously more rational to assume that a given *percentage* deviation has the same significance for the large as for the small animal, than that a given *absolute* deviation has the same significance for the large as for the small animal.

Equation (13.2) is interpreted as meaning that increasing X by 1 per cent is associated with a differential increase in Y by b per cent. Thus, assuming that in equation (13.2), Y represents metabolism or surface area and X represents body weight and the value of the exponent b is 0.7, then increasing body weight by 1 per cent is associated with a differential increase in metabolism or in area by 0.7 per cent; doubling body weight (increasing it by 100 per cent) is associated with a metabolic or area increase not of 100 per cent but of 70 per cent.

The value of the exponent represents *differential* or *very small* relative change as com-

puted by the differential calculus. The relation between the differentially computed and conventionally computed changes is indicated in Fig. 13.4.

The exponent is the actual slope of the curve when plotted on logarithmic coordinate paper; it is the ratio $\frac{Y_1 - Y_2}{X_1 - X_2}$, which, if desired, can be measured by a pair of dividers, "by inspection", or by the method of least squares, as illustrated in the appendix to this chapter.

Instead of relating Y (metabolism, area, etc.) to weight alone, W^b or X^b , we may include another independent variable such as height, H^m . Du Bois²⁵ reasoned that since area is a bidimensional measurement, both sides of the equation relating area to size should be bidimensional. In order to keep the formula containing weight and height bidimensional, it was written in the form

$$A = CW^{1/a}H^{1/b}$$

and by trial the values of a and b were found that keep the form bidimensional. In this way it was found that the formula

$$A = 71.8W^{.425}H^{.725}$$

is bidimensional³³ and best represents the data. This is the well-known Du Bois height-weight or linear formula for estimating surface area of humans.

Cowgill and Drabkin³⁴, working with dogs, concluded that the value of m , that is, the exponent of H in the Du Bois formula, is not 0.725, but 1.0.

All the above mentioned relations between surface area and body size may be represented by the equation

$$A = aH^mW^n$$

According to the general assumption that weight varies with the $\frac{2}{3}$ power of body weight, the value of m is zero; according to Cowgill and Drabkin's formula, it is 1; according to Du Bois formula, it is 0.725.

What is the value of m ? Is it 0, 1, or 0.725?

The answer may be formulated graphically as follows:

Equation (13.2)

$$A = aW^b \quad (13.2)$$

is changed to

$$A = aW^bH^m \quad (13.2A)$$

in which A is area, W is weight, H is height.

Then

$$\frac{A}{H^m} = aW^b \quad (13.2B)$$

and, on taking logarithms,

$$\log \frac{A}{H^m} = \log a + b \log W \quad (13.2C)$$

³³ Example of bidimensional writing of the area formula: Dimensionally, area, A , is height squared, H^2 , and weight is height cubed, H^3 ; height is the cube root of weight, $W^{\frac{1}{3}}$, so that

$$A = W^{.425}H^{.725}$$

may be written dimensionally

$$\begin{aligned} H^2 &= H^2 \times .425 H^{.725} \\ &= H^{1.275} H^{.725} \end{aligned}$$

$$\therefore H^2 = H^2$$

³⁴ Cowgill, G. R., and Drabkin, D. L., *Am. J. Physiol.*, **81**, 36 (1927).

Fig. 13.5—The relation of area, A , and of basal energy metabolism, E , to body weight, W , and height, H , in man. The ratios $\frac{A}{H^m}$ are plotted against weight. The most nearly straight line is obtained when m is 0.4. On increasing the value of m the resulting curve tends to break up into 3 segments. The breaks are distinct when $m = 1$ (value employed by Cowgill and Drabkin for dogs), or 0.725 (value employed by Du Bois and Du Bois for man). The star represents Mrs. McK (see Du Bois and Du Bois) weighing 204 lbs and having the height of a 12-year old girl. Note the position of the star for various values of the exponent m . Note that when $m = 0$, that is, when height is omitted, the distribution of the metabolism data is satisfactorily linear, with a slope (value of b) of 0.685.

which indicates that plotting logarithms of the ratios of area to height, raised to the power m , against the logarithms of weight, should give a straight line of slope b . Fig. 13.5 represents such ratios for human surface-weight data from birth to maturity.

The lowest curve in Fig. 13.5 represents the ratios of area to simple height, to $H^{1.0}$, plotted against weight on a logarithmic grid (equivalent to plotting $\log A/H$ against $\log W$). The curve is seen to be made up of three fairly distinct segments. The equations for each of the three segments are given on the curve. According to equation (13.2C), the plot of $\log A/H$ against W should result in a straight line while Fig. 13.5 shows that it is not a straight line; therefore, either equation (13.2C) does not represent the data, or the value of m is not 1; in other words, this curve precludes the value of m being unity, 1.0, as assumed by Cowgill and Drabkin³⁴ for dogs.

The second curve from the bottom represents a similar plot when m is assumed to be 0.725, the value assumed by Du Bois and Du Bois³⁵ for man. When the value of m is 0.725, the distribution of the data points more nearly approaches a straight line.

In similar manner we assumed the value of m to be 0.5, 0.4, 0.3, and 0, and the resulting values of A/H^m were plotted against W . Looking over the chart we concluded by inspection that the best agreement between observed and computed values is obtained when $m = 0.4$. We included in these computations the data by Bradfield³⁴, Du Bois and Du Bois³⁵, Frontali³⁶, Lissauer³⁷, Takahira³⁸, and Wörner³⁹, a total of 133 measurements, and with two exceptions, all the data points are within 10 per cent of the average.

The results in Fig. 13.5 lead to the conclusion that for individuals of "normal" build the equation relating area to weight and to height is

$$A = 240 H^{.40} W^{.53} \quad (13.5)$$

contrasted to Du Bois'

$$A = 71.84 H^{.725} W^{.425}$$

in which A is surface area in square centimeters, H height in centimeters, and W weight in kilograms. Equation (13.5) was used in preparing Fig. 13.6 for predicting surface area from weight and height in man.

But for individuals of "normal" build it is not really necessary to take height into consideration, because as shown in the top curve of Fig. 13.5 the equation

$$A = 1000 W^{.685}$$

is satisfactory.

As previously noted, introducing a linear measurement in the formula does not improve its predictability for *farm animals*, although it does so remarkably well for man. The age-weight-height interrelation for man is of quite a different order than for farm animals (Chs. 16 and 17).

13.5: Relation of basal energy metabolism to body weight in mature animals of different species. The metabolism data from mice to elephants in Table 13.1 were plotted on logarithmic coordinate paper and equation (13.2) fitted by the method of least squares. The result is shown in Fig. 13.7. The value of b , the slope of the curve on the logarithmic paper, is 0.73, meaning that doubling body weight is associated with a differential metabolic increase

Fig. 13.6—A chart for estimating surface area of man from the formula given on the chart.

of 73 per cent. The average numerical value of the ratio $\frac{\text{Cal/24 hours}}{\text{kg}^{0.73}}$ is 70.5, meaning that the average basal metabolism of the animals is 70.5 Cal per 24 hours per $\text{kg}^{0.73}$. The deviations from the average are given for each value in Table 13.1.

Benedict⁴⁰, criticized this result because the metabolism of the dwarf mouse, marmot, boar, bull, and elephant deviate considerably from this average (Table 13.2). Our reply is that the metabolism values for these animals represent special cases. The dwarf mouse is a hypopituitary and a hypothyroid animal (this is the reason for its dwarf size); it lacks normal metabolic mechanisms. The marmot is a hibernating animal, bordering between homeothermy and poikilothermy (its rectal temperature may drop to 3° C during hibernation). In other words, the unusually low metabolism per

Fig. 13.7—Basal metabolism of mature animals of different species, from mice to elephants, plotted against body weight on a double-logarithmic grid. The rising curve represents metabolism per animal per day; the declining curve represents the metabolism per kg body weight per day, both plotted against body weight. The rising curve is represented by the equation $\text{Cal} = 70.5 \text{ kg}^{0.734}$ or $\text{Cal/Kg}^{0.734} = 70.5$. The declining curve has the equation $\text{Cal/kg} = 70.5 \text{ kg}^{-0.266}$. (Note error in the equation on the declining curve in the chart—the kg was omitted by oversight.) The sum of the exponents of the rising and declining curves is 1.0 ($0.734 + 0.266 = 1.0$). The data represented by the crosses were omitted in computing the equation. The numerical data are given in Table 13.1, page 388-389. The slope of the rising curve, 0.73, means that an increase in body weight of 100 per cent is associated with an increase in basal metabolism of about 73 per cent. Note the consistent distribution of the data about the straight line.

$\text{kg}^{0.73}$ for the marmot is a species characteristic, not due to *size as such*. The high values for the boar, bull and elephant reflect technical difficulties in measuring metabolism of these temperamental animals. At any rate, the deviations do not appear to be due to *size as such* but to other factors, and all we claim is that the ratio of metabolism to the 0.73 power of weight is independent of body size *as such*: while the metabolism per kilo changes *systematically* from 8 Cal/kg for the elephant to 200 Cal/Kg for the mouse; the metab-

⁴⁰ Benedict,⁹ and Table 13.2.

olism per $\text{Kg}^{0.73}$ shows no *systematic* change with changing body weight. This is as true for Benedict's data, Table 13.2, as for the data in Table 13.1.

Fig. 13.8 shows that the metabolism of mature *birds* of different species varies more nearly with the $\frac{2}{3}$ power of body weight than with the 0.73 power, as appears to be the case with mammals.

Fig. 13.8—Basal metabolism of mature birds of different species plotted from data by the authors indicated in the charts.

Fig. 13.9 compares the metabolism of individual *growing* animals with the average curve in Fig. 13.7 for *mature* animals of *different* species. The deviations are so great that we decided to devote a special chapter (14) to the relation of metabolism to weight in the same growing animals.

Fig. 13.7 shows that the numerical value of a of the ratio $\frac{\text{Cal/day}}{\text{kg}^{0.73}}$, varies with the units employed. It is 70.5 when weight is in kg and heat in Cal/24 hours; 39.5 when weight is in pounds and heat in kilograms; and 156.8 when weight is in pounds and heat is in Btu.

Fig. 13.9—A comparison of the weight curves of metabolism of growing animals with the broken curve of the equation $Q = 70.5M^{.73}$. The declining curves represent metabolism per kg as compared to the declining broken curve from Fig. 13.7, namely $Q = 70.5M^{-.37}$.

As previously explained, over a century ago Sarrus and Rameaux suggested that either surface area or the square of linear size or, what amounts to the same, the $\frac{2}{3}$ power of weight be used as reference base for heat production and dissipation.

In 1916 Krogh⁴¹ suggested the use of a power of weight as reference base. In 1932

⁴¹ Krogh, A., "The respiratory exchange of animals and man," New York, 1916.

Kleiber⁴² reported that the $\frac{2}{3}$ power of weight is a good reference base. At about the same, employing a different method of analysis and different data, we published⁴³ our results reporting the 0.73 power of weight as reference base. This report was extended⁴⁴ in 1934, demonstrating that not only basal energy, but also endogenous nitrogen and neutral sulfur tend to vary with the 0.73 power of body weight. The Conference on Energy Metabolism⁴⁵ tentatively adopted the 0.73 power of body weight as reference base for energy metabolism. Benedict⁴⁶ criticized this reference base on the ground that the metabolism of the dwarf mouse, marmot, bear, bull, and elephant deviated grossly from the predicted values (see Table 13.2).

As further argument against using the 0.73 power of body weight as reference base, Lee⁴⁷ reported that a linear equation (13.4) represented metabolism data on rabbits as well as a power equation (13.2). However, Lee's equation

$$Y = 39.5X + 22.5$$

shows it to be irrational because extrapolation gives a metabolism of 22.5 Cal/hr for zero body weight. We worked over Lee's data with the result shown in Fig. 13.10, on a logarithmic grid in the upper left and on an arithmetic grid on the lower right corner. It appears that for the given range of data there is not much difference between the arithmetic and logarithmic fit; the slope of the logarithmic line is 0.82 rather than 0.73, as in Fig. 13.7.

To check further the question as to whether within the species a linear equation is as good as a logarithmic, we measured⁴⁸ the basal metabolism of four groups of mature Rhode Island Red fowls, normal, and bantam (small) varieties. The result in Fig. 13.11 shows that, if both varieties are included, the fowl curve coincides with the general mammalian curve in Fig. 13.7; the slope range for the various groups is from 0.70 to 0.74, and they practically coincide with curve (3), representing the mouse-to-elephant curve in Fig. 13.7. If, however, the equation is fitted to the larger variety alone (omitting the bantams) the slope is very low, 0.30 to 0.54, perhaps due to the fact that the larger birds of the larger variety were relatively fatter. Our result differs from Lee's in that the slope is 0.74 or less, never 1.0 (*i.e.*, never linear).

There is a considerable body of data on metabolism of dogs, and it seems interesting to see how metabolism varies with body size. Are the slopes nearer 1.0 (Lee) or $\frac{2}{3}$ (surface law)? We plotted in Fig. 13.12 several well-known sets of data⁴⁹, giving a slope not of 1.0, but 0.61 for Rubner's data, and 0.57 for Lusk's and Kunde's data. In no case did the slope approach unity.

Finally, Fig. 13.13 brings together on a logarithmic grid the data from Figs. 13.7, 13.10, and 13.12; it shows, by the curved line, the result of "forcing" a linear equation (by the method of least squares) on the data in Table 13.1.

We thus conclude that the basal energy metabolism of mature animals of different species tends to vary with approximately the 0.7 power of body

weight and suggest that $\text{Kg}^{0.7}$ be taken as reference base for comparative basal metabolism measurements.

13.6: Relation of endogenous nitrogen, creatinine, and neutral sulfur excretion to body weight in mature animals of different species. The 0.7 power of body weight is not only a good reference base for basal *energy* metabolism but also for basal *protein* metabolism, or endogenous nitrogen and neutral sulfur excretion.⁵⁰ This is demonstrated in Figs. 13.14, 13.15, and

Fig. 13.10—Metabolism of Lee's rabbits plotted on logarithmic (upper left) and arithmetic (lower right) paper compared with the mice-to-elephant curve from Fig. 13.7.

13.16, plotted from data in Tables 13.4 a and b and 13.6. The value of the exponent is seen to range from 0.72 (Fig. 13.14) to 0.74 (Fig. 13.16).

The creatinine excretion, however, varies not with the 0.7 power but more directly with weight. This is shown in Fig. 13.17, plotted from Table 13.5. In other words, creatinine cannot be taken as an index of basal energy metab-

⁵⁰ Brody, S., Procter, R. C., and Ashworth, U. S., "Basal metabolism, endogenous nitrogen, creatinine, and neutral sulfur excretions as function of body weight," Mo. Agr. Exp. Sta. Res. Bull. 220, 1934.

Fig. 13.11—Metabolism of two varieties (bantam and normal) of Rhode Island Red fowls compared with the mice-to-elephant equation of 13.7. The curves of the two virtually coincide, the slope being nearly 0.73. If, however, the bantams are omitted, the slope is very low.

Fig. 13.12—Metabolism of three groups of dogs indicating a slope of 0.6.

Fig. 13.13—The curves from Figs. 13.7, 13.10, and 13.12 are brought together on a logarithmic grid. Also a linear equation is shown when arbitrarily "forced" on the data by the method of least squares.

Fig. 13.17—Creatinine as function of body weight, plotted from Table 13.5.

olism, as was suggested by Palmer, Means, and Gamble.⁵¹ These authors reported that eight men produced on the average 0.98 Cal per mg creatinine, and that nine women produced on the average 1.26 Cal per mg. We have shown⁵² that the course of creatinine excretion in growing dairy cattle does not parallel that of heat production. At a body weight of 40 kg, four Cal

Fig. 13.18—Prediction curves for energy and protein catabolism as functions of body weight, plotted from Table 13.7.

were produced per mg creatinine; at a body weight of 400 kg, only one Cal was produced per mg creatinine.

The parallelism between basal energy metabolism, endogenous nitrogen excretion, and neutral sulfur excretion—but not creatinine excretion—is illustrated graphically in Fig. 13.18, and in the prediction Table 13.7. Such

⁵¹ Palmer, W. W., Means, J. H., and Gamble, J. L., "Basal metabolism and creatinine elimination," *J. Biol. Chem.*, **19**, 239 (1914).

⁵² Mo. Agr. Exp. Sta. Res. Bull. 143, pp. 58-61, 1930.

parallelism means that the ratio of endogenous urinary or total nitrogen to basal energy metabolism tends to be the same in small and large animals, namely, about 2 mg nitrogen per Cal. Practically, this means that the nutritive ratio, or the ratio of energy to nitrogen in a maintenance ration, is independent of body weight.

Historical and explanatory notes: In 1928 Terroine and Sorg-Matter⁵³ reported data on the ratio of total endogenous nitrogen excretion, *including fecal*, to basal energy metabolism in mature animals of different species, mice, rats, pigeons, chickens, and rabbits, and found it to be approximately constant, namely 2.3 to 2.9 mg N per Cal, as indicated by the following table:

Animal	Mg total endog. N per kg-hr	Cal basal metabolism per kg-hr	Mg N per Cal
Mouse	34.8	12.0	2.90
Rat	18.8	7.8	2.41
Pigeon	18.8	6.5	2.89
Chicken	10.6	4.6	2.30
Rabbit	9.0	3.4	2.65
Dog	6.7	2.4	2.80
Man	2.2	0.933	2.32

They also reported that changes in external temperature have the same relative influence on total endogenous nitrogen excretion as on basal metabolism; that the ratio of total endogenous nitrogen to basal energy metabolism remains constant, regardless of temperature; and that, therefore, the minimum nitrogen excretion, like the minimum energy metabolism, is attained only at thermal neutrality.

In 1935 Smuts⁵⁴ reported similar data (Table 13.4b), but on endogenous urinary nitrogen alone (not including fecal N), and the energy metabolism was measured on the *same* animals (which Terroine did not do). The conditions were strictly basal. The range in live weight of Smuts' animals is much wider (from 20-g mice to 79-kg pigs) than the range of Terroine's animals (from 15-g mice to 1.6-kg chickens).

Smuts' results confirmed Terroine and Sorg-Matter that the ratio of endogenous nitrogen to basal metabolism is remarkably constant for animals of different live weight, as indicated by the following ratios of mg urinary nitrogen to Calories basal metabolism: mice, 1.92; rats, 2.00; rabbits, 2.04; pigs, 2.10; average of all measurements, 1.99. If one recalls that Terroine reported the ratios in terms of total (including fecal) nitrogen to Calories, while Smuts reported his data in terms of urinary nitrogen to Calories, the differences between the N/Cal ratios of these two investigators probably disappear.

Incidentally, Bonnet⁵⁵ found that the N/Cal ratios of poikilotherms, namely frogs and tortoises, remain constant at different environmental temperatures, ranging from 2° to 30°; they rise and fall together at a constant ratio with temperature changes. In the frog the average of this ratio was 7.2; but in the tortoises it was 2.8, very near the average found by Terroine and Sorg-Matter for homeotherms. Within each of these species, however, this ratio remained constant for different environmental temperatures. Bonnet suggests that reptiles are "biochemically intermediate" between homeotherms and poikilotherms.

Fig. 13.19—A comparison on arithlog grid of the course of change of endogenous nitrogen with basal metabolism and with body weight with time on N-free diet (Fig. 1, p. 8, Missouri Res. Bull. 223). See page 353 for discussion.

Creatinine: Fig. 13.17, based on Table 13.5, includes data on creatinine nitrogen excretion of animals ranging in weight from 0.02 to 800 kg, thus furnishing a broad basis for generalization. Equation (13.2) was fitted to the data by the method of least squares. It appears that for the Missouri data, which represent growing animals, and for animals of different size of the *same species*, the creatinine excretion is directly proportional to body weight (the value of the exponent is near unity). For men of different weight the

Fig. 13.20—Method of collecting urine from rats (Fig. 2, Missouri Res. Bull. 228, p. 9).

creatinine excretion increases even more rapidly than body weight (the exponent is 1.29). But for mature animals of *different species* the creatinine excretion increases with the 0.83 to 0.89 power of body weight. Since the endogenous nitrogen increases with but the 0.72 power of body weight, the creatinine nitrogen percentage in the endogenous urinary nitrogen increases with increasing body weight. The ratio of creatinine to total endogenous urinary N rises with increasing body weight from 4 per cent for 20-g animals to 30 per cent for 1000-kg animals. *Creatine nitrogen does not, therefore, vary directly (i.e., linearly) with either endogenous nitrogen metabolism or with basal metabolism, but more nearly with body weight.*

Neutral sulfur: The data points in Fig. 13.16 (plotted from Table 13.6) for neutral

sulfur seem to be widely scattered, but the average slope is of the same order of magnitude as the slopes of the basal metabolism and endogenous nitrogen curves.

As regards the erratic distributions of the neutral-sulfur data, Folin⁵⁶ reported that neutral sulfur excretion tends to be independent of the protein intake. No dietary precautions would, therefore, seem to be needed. A large literature has, however, recently developed indicating that Folin's conclusion with regard to the constancy of neutral sulfur is not absolutely true. Since no special dietary precautions were taken in securing the neutral sulfur data, and since the diet is an influencing factor after all, the erratic distribution of the data becomes understandable.

According to Amann⁵⁷, the neutral sulfur excretion is the same on low as on "normal" protein diets, but it is increased on high-protein diets. When the dietary protein is increased 15 times, the neutral sulfur excretion is tripled. The amount of neutral sulfur is thus not strictly endogenous; it is not altogether independent of the diet, although it is constant in comparison with total sulfur excretion. According to Amann, the factors affecting the metabolism of energy also affect the excretion of neutral sulfur; but the neutral sulfur excretion is not definitely proportional to calorie production, as is the case with endogenous nitrogen.

13.7: Summary. Basal energy metabolism does *not* vary directly with simple body weight, $W^{1.0}$; with $W^{\frac{1}{2}}$, which would be proportional to surface area if different animals were geometrically and physically similar, which they are not; nor with anatomic surface area, which is not a constant for a given living animal. Basal metabolism varies directly with what we called, for lack of a more direct designation, *metabolically effective body weight*, defined by W^b . The W represents body weight (we also used interchangeably the symbols M and X); b represents the slope of the curve when plotted on logarithmically coordinate paper, and is easily computed from the given data. By this method we found that the value of b is 0.73 for the data in Table 13.1, including animals ranging in weight from mice to cattle, and perhaps elephants.

Interestingly enough, the value of b also turned out to be 0.73 for Benedict's monumental data given in Table 13.2, provided that several evidently atypical data are omitted. If these atypical data are not omitted, the value of b for Benedict's data is 0.76.

On the other hand, the value of b for dogs of different size is only 0.6; for mature birds of different species the value of b ranges for several sets of data from 0.62 to 0.70. For mature Rhode Island Red fowls of two varieties, it was 0.73 if both varieties were included, and only 0.5 if the bantam variety was excluded. For mature rabbits of different size, as reported by Lee, the

value of b was 0.82. It is particularly variable for man, depending on the age range, although we suggest different constants for the DuBois linear formula (Fig. 13.6). We are not, however, concerned with human data, which are taken care of by DuBois formula. While we employ the reference base $W^{0.73}$ throughout this book, yet because of these variations, we are inclined to drop the second decimal (which gives the impression of greater constancy or precision than is justified by the variability of the data) and suggest that $W^{0.7}$ be adopted for the reference base for basal metabolism; that increasing

Fig. 13.21a—Method of collecting cow's urine and feces into separate containers as used in our laboratory.—The motor and gear assembly keep the belts turning continuously toward the center. Feces which fall on the belts are carried through the trapdoors and scraped off into the tubs. Urine flows down the inclined belts and is directed by the funnel-shaped pans into the bottles. This apparatus was patterned after the installation by Ritzman and Benedict, N. H. Agr. Exp. Sta. Bull. 240.

body weight 100 per cent tends to be most nearly associated with a differential metabolic increase not of 100 per cent but only of 70 per cent.

This reference base $W^{0.7}$ has broader implications than appear, because it is also the reference base for many other processes. Thus the endogenous urinary nitrogen and sulfur excretion also vary with $W^{0.7}$. Creatinine, however, though a component of the endogenous nitrogen, reflects more nearly the mass of the supporting muscles than that of the vital visceral organs and so varies more nearly with $W^{1.0}$ than with $W^{0.7}$.

Special attention is given to the "surface law", the best formulation of which was made over a century ago but which is frequently re-discovered by

Fig. 13.21b—See caption of 13.21a.

Fig. 13.21c—See caption of 13.21a.

numerous investigators. This is typical of much scientific work, and of life in general: continuous forgetting and re-discovering of old truths.

The "surface law" is reasonable enough except that anatomic surface cannot be measured with precision; that physiologic, or "free", or "metabolically effective", surface is not identical with anatomic surface; that external surface is not the direct "cause" of a given metabolic level, although the correlation of metabolic level with surface area may have been an evolutionary prerequisite for survival—an evolutionary, or "remote cause".

The direct control of the metabolic level resides not in the external surface but in the neuro-endocrine system which, for geometric and mechanical "reasons" discussed in the text, tends to vary in size with surface area rather than with simple body weight. So it comes about that the size of the neuro-endocrine components, the surfaces, the heat dissipation, and the heat production all tend to vary in parallel (Ch. 17). They may all be said to vary with W^b , and the value of b tends to be near 0.7. It will be shown presently that the quantity of milk-energy production (Chs. 21, 22) and of egg-energy production (Ch. 23) likewise tends to vary with $W^{0.7}$, as does basal energy metabolism and endogenous protein metabolism. This brings out the broad significance of the proposed reference base $W^{0.7}$, which may be termed "physiological" weight in contrast to $W^{1.0}$, which is the "physical" or gravitational weight.⁵⁸ These interrelations and the importance of W^b will be further discussed in Chapters 14, 15, 17, 21, 22, 23, and 24. In the meantime it is suggested that $W^{0.7}$ be tentatively adopted as reference base for basal-energy metabolism, endogenous nitrogen excretion, milk-energy production, egg-energy production and related processes.

The following tables are self-explanatory summaries and "predictions".

¹ From F. G. Benedict, "Vital Energetics": A study on comparative basal metabolism. Carnegie Inst. Washington, Pub. 503, 1938, pp. 175-6. The last 3 columns were computed by us.

² Computed by the writer from equation $Q = 72.18 M^{.7317}$ which may be rounded to $Q = 72.2 M^{.73}$. This equation does not include figures in parentheses. The standard error of estimate is +15% and -13%. The index of correlation is 0.998, and the coefficient of correlation of Cal/kg.^{.73} is 15%. If the figures in parentheses are not omitted, the equation is $Q = 69 M^{.76}$, with standard error of estimate of +27% and -21%.

TABLE 13.3

Rubner's¹ classic tabulation indicates that heat production per kg small mature dog is larger than per kilo large one, but nearly the same per square meter surface area. We found the following least-squares equation for Rubner's data: $Q = 142M^{.613}$, with $+S_R = 5.7\%$ and $-S_R = 5.4\%$.

Dog	Body Weight (kg.)	Heat Production in Calories per 24 Hours		
		Per Kg	Per Sq. Meter Body Surface	Per Kg. ^{.413}

13.8: Appendix.

13.8.1: Fitting equation $Y = aX^b$ to data. As outlined in the introduction the equation

$$Y = aX^b \quad (13.2)$$

may be written

$$\log Y = \log a + b \log X \quad (13.3)$$

which has the same form as the linear equation

$$Y = a + bX \quad (13.4)$$

and that (13.3) yields a linear distribution of data on logarithmic coordinate paper, as (13.4) yields a linear distribution of data on arithmetic paper. The first procedure, then, is to plot the data on logarithmic coordinate paper to determine whether the function is logarithmic.

It is, moreover, very desirable to plot data in such manner as to give a linear distribution of the data, for two reasons: (1) the eye is extremely sensitive to deviations from a straight line, and the degree of closeness of the grouping of the data around the straight line is a simple index of the degree of the reliability of the data; (2) it is very much easier to draw an average straight line than a curve. With some experience, such an average line drawn free-hand may be nearly as good as one fitted by the method of least squares. The equation can then be fitted to the line drawn in by inspection. Two points are read from the line and the equation obtained by the method outlined at the end of this section.

The second procedure of fitting equation (13.3) to the data is by the method of least squares. The problem is to find the numerical values of b and of $\log a$ so that the sum of the positive and negative deviations (vertical differences between the data points and the line representing the resulting equation) is zero, and the sum of the squares of the deviations is a minimum.

Since the equation has two unknowns, we must have two equations (I and II) to solve it. These two "normal equations", are obtained by multiplying the equation first by the coefficient of $\log a$, then by the coefficient of b .

Multiplying the equation by 1, which is the coefficient of $\log a$, we get

$$\log Y = \log a + b \log X$$

Then we sum up all points, and get

$$\text{I. } \Sigma(\log Y) = N(\log a) + b\Sigma(\log X)$$

(The symbol Σ , Greek Sigma, stands for "sum of"; N represents the number of data points.) This is our first "normal equation", I.

Having obtained the first "normal equation", I, by multiplying the equation by the coefficient of $\log a$, we next proceed to get the second "normal equation", II, by multiplying it by the coefficient of b , namely by $\log X$. Multiplying by $\log X$ and summing, we get

$$\text{II. } \Sigma \log X \cdot \log Y = \log a \Sigma \log X + b \Sigma (\log^2 X)$$

This is our second "normal equation", II. The two "normal equations" that we must solve are, therefore,

$$\text{I. } (\log Y) = N \log a + b (\log X)$$

$$\text{II. } (\log X \cdot \log Y) = \log a (\log X) + b (\log^2 X)$$

The application of the method of least squares is illustrated on the following set of actual metabolism data.

From the above two "normal equations" we see that the values we need to calculate are:

$$(\log Y); (\log X); (\log X \cdot \log Y); (\log^2 X); N$$

which are shown in the following table:

Species	Body Wt. X kg.	$\log X$	Metabolism Y Cal/day	$\log Y$	$\log X \cdot \log Y$	$(\log^2 X)$	$(\log^2 Y)$
Mouse.....	0.0276	-1.5591	5.0	0.6990	-1.08981090	2.43079281	0.48860100

Summations.....		12.6173		27.7831	55.07818780	43.02130707	91.98528765

The number of data points, N , is 10; $(\log^2 Y)$ is given, to be used later in computing the standard error of estimate.

$$\text{I. } \Sigma (\log Y) = N \log a + b \Sigma (\log X)$$

$$\text{II. } \Sigma (\log X \cdot \log Y) = \log a \Sigma (\log X) + b \Sigma (\log^2 X)$$

$$\text{I. } 27.7831 = 10 \log a + 12.6173 b$$

$$\text{II. } 55.07818780 = 12.6173 \log a + 43.02130707 b$$

Dividing each equation by the coefficient of $\log a$, we get:

$$\text{I. } 2.7783100 = \log a + 1.2617300 b$$

$$\text{II. } 4.3652911 = \log a + 3.4097079 b$$

We can now eliminate one of the unknowns, $\log a$, by subtracting equation I from equation II

$$1.5869811 = 2.1479779 b$$

$$\therefore b = 0.73882562$$

To solve for $\log a$, we substitute the value of b in one of the above equations. Substituting in equation I,

$$2.7783100 = \log a + (1.2617300) (0.73882562)$$

$$\log a = 2.7783100 - 0.9321984$$

$$\log a = 1.8461116; \text{antilog of } \log a = 70.2.$$

Inserting the numerical values of a and b in the original equation, we get

$$Y = 70.2 X^{0.74}$$

which is the solution of the problem.

We now need a test to ascertain the scatter of the data points about the line of the above equation. This test is called the "standard error of estimate" the formula for which is*:

$$S_{\text{est}}^2 = \frac{d^2}{N'}$$

in which d represents a single deviation of the actual value of Y from the value computed from the equation, and N' is the "degrees of freedom". The "degrees of freedom" are the number of data points less the number of constants in the equation.

The following short-cut formula is more suitable for solving our problem:

$$S_{\log Y \cdot \log X}^2 = \frac{\Sigma (\log^2 Y) - \log a \Sigma (\log Y) - b \Sigma (\log X \times \log Y)}{N'}$$

* Ezekiel, M., "Methods of Correlation Analysis," 1930.

Substituting:

$$\begin{aligned}
 S_{\log y \cdot \log x}^2 &= \frac{91.98528765 - (1.8461116 \times 27.7831) - (0.73882562 \times 55.07818780)}{10 - 2} \\
 &= \frac{91.98528765 - 51.29070319 - 40.69317640}{8} \\
 &= \frac{0.00140806}{8} = 0.000176075
 \end{aligned}$$

$$S_{\log y \cdot \log x} = 0.0133$$

This standard error is the difference between two logarithms, and since the difference between two logarithms is a ratio, we may express the standard error in per cent. To do this we must assume a base, such as 100, along the equation line, to work from. Taking 100 for our base line, the logarithm of 100 is 2.000. Adding the standard error to it we get 2.0133. The antilog of this is 103.1, which is 3.1 per cent above our assumed base.

The negative standard error in per cent will, of course, be smaller than the positive because of the principle of logarithms. Using the same base as before, but subtracting instead of adding

$$2.00 - 0.0133 = 1.9867$$

The same result would have been obtained had we chosen any other point on the equation line as our base. The standard error for the equation in per cent, is then

$$+S_R = 3.1 \text{ per cent}$$

$$-S_R = 3.0 \text{ per cent}$$

This value of the "standard error of estimate" means that two-thirds of the time the metabolism computed from this equation will agree with the observed metabolism within +3.1 per cent and -3.0 per cent.

When it is desired to compute not only the regression coefficients but also other statistical measures, the computations may be simplified* by reducing the sum of the squares and products of the observed values (in this case, of the logarithms of the observed values) to the sum of squares and products of deviations from the proper means.

Letting observed values be denoted by capital letters, and deviations from mean by small case letters, after the fashion of Snedecor†, the desired reductions may be effected as follows:

$$\begin{array}{rcl}
 \Sigma \log X & = & 12.6173 \\
 \left(\frac{\Sigma \log X}{N} \right) & = & 1.26173 \\
 \left(\frac{\Sigma \log X}{N} \right) \Sigma \log X & = & 15.919626 \\
 \log^2 X & = & 43.021307 \\
 \hline
 \Sigma \log^2 X & = & 27.101681 \\
 \\
 \Sigma \log Y & = & 27.7831 \\
 \left(\frac{\Sigma \log Y}{N} \right) & = & 2.77831 \\
 \log^2 Y & = & 91.985288 \\
 \left(\frac{\Sigma \log Y}{N} \right) \Sigma \log Y & = & 77.190065 \\
 \hline
 \Sigma \log^2 Y & = & 14.795223 \\
 \\
 N & = & 10 \\
 \\
 \Sigma \log X \cdot \log Y & = & 55.078188 \\
 \\
 \left(\frac{\Sigma \log X}{N} \right) \Sigma \log Y & = & 35.054771 \\
 \hline
 \Sigma \log X \cdot \log Y & = & 20.023417
 \end{array}$$

*Method suggested by Hudson Kibler.

†Snedecor, G. W., "Statistical Methods," 1937.

The regression coefficients, a and b , the standard error of estimate, $S_{\log y \cdot \log x}$ or $+S_{y \cdot x}$, and the coefficient of correlation, ρ may then be computed as follows:

$$\log Y = \left(\frac{\Sigma \log Y}{N} \right) + \frac{\Sigma \log x \cdot \log y}{\Sigma \log^2 x} \left[\log x - \left(\frac{\Sigma \log x}{N} \right) \right]$$

$$\log Y = 2.77831 + .738826 \log X - .93220 = 1.84611 + .738826 \log X$$

$$Y = 70.2 X^{0.74}$$

$$S^2_{\log y \cdot \log x} = \frac{\Sigma \log^2 y - b(\Sigma \log x \cdot \log y)}{N - 2} = \frac{14.795223 - 14.793821}{8}$$

$$= .00017525$$

$$S_{\log y \cdot \log x} = .01324$$

$$+S_{y \cdot x} = [(\text{antilog } .01324) - 1]100 = (1.031 - 1)100 = 3.1 \text{ per cent}$$

$$-S_{y \cdot x} = \frac{3.1}{1.031} = 3.0 \text{ per cent}$$

$$\rho^2 = \frac{b(\Sigma \log x \cdot \log y)}{\Sigma \log^2 y} = \frac{14.793821}{14.795223} = .99905$$

$$\rho = .9999+$$

If we wish to evaluate b by inspection from only two data points (see p. 402) as for example from the weights and metabolism of the mouse and the elephant, we may do so by the equation

$$b = \frac{\log Y_{(\text{elephant})} - \log Y'_{(\text{mouse})}}{\log X_{(\text{elephant})} - \log X'_{(\text{mouse})}} \\ = \frac{4.4903 - 0.6990}{3.5835 - 1.5591} = 0.737$$

Therefore, after taking logarithms on both sides and solving for b , we have,

$$Y:Y_1 = X^b:X_1^b \\ = \frac{\log Y - \log Y_1}{\log X - \log X_1}$$

There is some objection to fitting a logarithmic equation to data by the method of least squares, because it involves squaring logarithms. To throw some light on this problem Feldstein and Hersh* made a comparative study of the constants obtained by computing them from the original data, and from the logarithms of the data. They found that while the two methods gave very similar results, the use of the logarithmic method was much less laborious. They were unable to establish any "certain criterion . . . for deciding which of the two methods is to be preferred."

The standard error of the exponent, b , they proposed is

$$S_b = \pm \frac{1 - \rho^2}{N - 2} \cdot \frac{\sigma \log y}{\sigma \log x} = \pm \sqrt{\frac{N \Sigma (\log^2 y) - [\Sigma (\log y)]^2}{N \Sigma (\log^2 x) - [\Sigma (\log x)]^2}}$$

It should be noted, however, that Schmalhausen† antedated Feldstein and Hersh in publishing a least-square solution of the exponent, b , and formulas for the standard errors of b and intercept a , and also in defending the use of the least-square solution of the logarithmic form of the simple parabola we are interested in.

13.8.2: Numerical values of $X^{0.73}$, $X^{3/4}$, $X^{2/3}$ corresponding to values of X : Sarrus and Rameaux, Bergmann, Rubner, Meeh and others assumed that the value of b is $2/3$ in the equation relating metabolism, Y , to body weight, X . In our study of the relation between metabolism and body weight of mature animals of different species, we found the value of b is 0.73 . Kleiber found the value of b to be near $3/4$.

According to our proposal for relating metabolism to X^b , metabolism should be related to $X^{2/3}$, or $X^{0.73}$, or $X^{3/4}$, depending on which of the values of b one accepts. In this chapter, metabolism is related to $X^{0.73}$, and the value of a , which might be termed specific metabolism, is computed from the equation $a = \frac{\text{Cal.}}{X^{0.73}}$, which is of the order of 70.5 when X is body weight in kg, or 39.5 when X is body weight in pounds. Kleiber evaluates a from the equation $a = \frac{\text{Cal.}}{X^{3/4}}$, which is of the order of 72 when X is body weight in kilos.

To save time computing the values of $X^{0.73}$, or $X^{3/4}$, or $X^{2/3}$, we present Table 13.8 giving a series of numerical values of X^b for corresponding values of X (body weight). If the desired values of X are not in the table, given values of X^b may be plotted against corresponding values of X , and the value of X^b read for the desired value of X .

Table 13.9. The numerical values of a and b in the formula surface area = a (weight) ^{b} . The area is given in sq. meters, weight in kg. (see p. 360).

	a	b	Remarks
Dairy cattle	0.14	0.57	50 Holsteins, birth to maturity.
Dairy cattle	0.15	0.56	Av. of 46 Jerseys and 50 Holsteins, birth to maturity.

Sheep	0.12	0.57	

Chapter 14

Metabolism and Pulmonary Ventilation in Relation to Body Weight During Growth

The embryo has no surface if the word surface be used in the physiological sense intended to convey to the reader the idea of an area from which heat is dissipated. *J. Barcroft*

14.1: Definitions. Fig. 13.7 shows a remarkably constant ratio of basal metabolism to $W^{0.73}$ in *mature* animals of *different species*, including the enormous body-weight range of 0.02 to 4000 kg (mice to elephants).

Such constancy cannot be expected during *rapid growth* for several reasons. First, there may be a *work-energy* cost (in the thermodynamic sense) of growth not separable from the basal metabolic cost (Ch. 3) which, of course, changes with advancing age and growth rate. Secondly, early life is essentially poikilothermic (Ch. 11); the thermoregulatory mechanisms are not called upon to function during prenatal life, so that it requires some time to develop their functions postnatally. Thirdly, the neuro-endocrine system involved in the thermoregulatory control of the metabolic rate does not attain maximal functional level until relatively late in life. For instance, the sex endocrines, adrenals, and thyroid influence energy metabolism, yet they do not mature until after puberty (Ch. 17). The brain, which is also said to be involved in the control of metabolism (Chs. 13, 17), does not attain the maximal metabolic level until age about 20 years in man, and 30 to 50 days in the rat^{1,2}; the situation is similar in the dog, cat, rabbit, and guinea pig. The muscular mass, which necessarily affects metabolism, increases in man from 25 per cent of the total body weight at birth to about 43 per cent at maturity.³

As regards surface area, the younger the organism the more rapidly the change in shape from the "simple" spherical to the complex form, including many bizarre structures (allantois and amniotic sacks, membranes, renal and other tubules, etc.), which serve as parts of the surface-area complex.

Extrapolating the metabolism-surface "law" to the earliest stages leads to a fabulous heat production sufficient to burn up the early embryo. Thus

¹ Himwich, H. E., *et al.*, *Am. J. Physiol.*, **125**, 601 (1939); **134**, 281 (1941); **137**, 327 (1942); **142**, 544 (1944).

² Tyler, D. B., and Harreveld, A., *Id.*, **136**, 600 (1942).

³ Wilmer, H. A., *Proc. Soc. Exp. Biol. and Med.*, **43**, 545 (1940). Latimer, H. B., *Growth*, **8**, 218 (1944).

extrapolating the equation $Y = 70.5 X^{0.73}$ (Fig. 13.7) yields the following fantastic values:

Weight (g.)	10	1	0.1	0.01	0.001	0.0001	0.000001
Cal/kg/day.	246	455	848	1578	2939	5472	18980

Fig. 14.1. Metabolism per unit surface area in rats as a function of age (upper section) and of weight (lower section). Plotted from Table 14.1.

The conclusion is that the metabolism per unit surface area, or per W^b (when b is $\frac{2}{3}$ to $\frac{3}{4}$), cannot remain constant during early growth, and that heat production per unit area must begin at a relatively low rate.

Because of the changing nature of the factors making up the heat-production complex in rapidly growing animals, we shall employ not the designation

“basal metabolism”, but “resting metabolism” when the metabolism is not post-absorptive and “fasting metabolism” when the resting metabolism is approximately post-absorptive. The following discussion is concerned with resting metabolism during *postnatal* growth—birth to sometime after puberty—in the form of age and weight curves of metabolism; and *prenatal* growth mostly in the form of total metabolism as function of birth weight.

Fig. 14.2. The same data as 14.1, but the total metabolism per day is plotted against body weight on logarithmic paper. Basal data are shown in the insert. The other data represent *ad libitum* feeding. The curves for the various phases of growth represent the equation $Y = aX^b$ fitted to the data by the method of least squares.

14.2: Metabolism in relation to body weight in the white rat, with notes on cerebral metabolism. The measurements were made⁴ at 30°C in an 8-chamber Regnault-Reiset volumetric apparatus (Fig. 12.11c) by the oxygen-consumption method. Windows in the chamber permitted activity observations; and as readings were taken every ten minutes for over an hour, observed activity could be eliminated from the averaging. The results, shown in Table 14.1a and Figs. 14.1 and 14.2, are thus metabolism during

⁴ Kibler, H. H., and Brody, S., *J. Nut.*, **24**, 461 (1942).

rest. Beginning with the thirty-second day, fasting (14 to 26 hours) as well as non-fasting data were secured. No attention was paid to the time of food intake preceding this age.

As explained in the foregoing section and shown in Fig. 14.1, the metabolism per unit surface area rises; in this case it rises from about 400 Cal/sqm/day near birth to 1100 or 1200 at the age of 40 days or body weight of 100 g. Thereafter the metabolism declines to about 800 Cal/sqm/day at the age of four months or weight of 300 grams. After this, there is further decline associated with aging, discussed in Chapter 18.

This is typical of most age curves of metabolism, and as noted in the preceding section, it parallels in the rat the age curve of metabolism of the brain.² Such parallelism, however, does not hold for man. "In the human there is a slow rise in cerebral metabolic rate from birth to twenty years of age; it then remains constant until the senium when there is a progressive fall. The total human basal metabolic rate, on the other hand, is maximal at approximately two years of age. We are, therefore, left with different relationships for cerebral metabolic rate and basal metabolic rate in rat and in human".⁵

The explanation of this brain-body metabolic difference in rat and man is perhaps due to differences in the brain-body growth-rate difference. Man's brain may continue active growth for a relatively longer period than the rat's (Chs. 16, 17), and we believe (Ch. 3) that the metabolic rate is closely associated with the growth rate. The more rapid the growth rate, the higher the metabolic rate, partly because of the "work" of growth, but mainly because the rapidly growing tissue is more youthful, "more alive", than the slow-growing or non-growing. "Retardation of growth is old age" (C. S. Minot, see Ch. 18). It is particularly worthy of note (Table 14.1) that the metabolism per square meter tends to parallel the rise and decline of the growth rate (Ch. 3).

When *total metabolism* is plotted against *body weight* on *logarithmic paper*, as in Fig. 14.2 (which represents the same data as Fig. 14.1), the data appear to be distributed in four segments. To each of these segments the equation $Y = aX^b$ was fitted. The meaning of the first break, between segments I and II, is not clear, but data obtained by a different method on different animals and at a different time substantiate its reality. The break between segments II and III coincides with weaning, but may be due to a change in method of measurement, from entire litters in a chamber with no control over activity to individual rats in a chamber, with elimination of activity.

The final break, although it may not be as definite as pictured, seems to be real and associated with a change in percentage growth rate. Preceding the break (at about 100 g body weight) metabolism increases with the 0.8 to 0.9 power of body weight (a 1.0 per cent increase in weight is associated with an 0.8 to 0.9 per cent increase in metabolism); following the break, during the

⁵ Himwich, H. E., Personal communication.

period of declining growth rate, metabolism increases with less than the 0.4 power of body weight. On a percentage basis, then, total metabolism increases more rapidly with weight during the period of rapid growth rate than during that of declining growth rate (Ch. 3).

Sex differences in metabolism at a given body weight become apparent after 45 days, and perhaps may likewise be attributed in part to differences in growth rates, the males being chronologically younger and growing more rapidly than the females of the same body weight.

Curve IX represents the relation of basal metabolism to body weight in mature animals of different species within the given weight range (Fig. 13.7). During the period of rapid percentage growth from weaning to 45 days, the metabolism (curve VI) of the rats is considerably higher than that of mature animals of different species; but as the rats approach their maximum body weights their metabolism approaches that of other species.

To summarize: when the resting metabolism of rats from birth to four months is plotted in terms of Calories per *unit area*, it rises steeply from birth (400 Cal/sqm/day) to the age of 40 days or to weight of 100 grams (1100 Cal/sqm/day for fasting and 1250 Cal/sqm/day for *ad libitum* feeding) and declines thereafter (800 Cal/sqm/day at four months). When plotted on logarithmic paper in terms of *total* metabolism against body weight, the distribution of the data indicates the presence of three breaks, one at the age of about ten days, one at weaning about three weeks, and one at about forty days. The first three segments have slopes ranging from 0.80 to 1.1 (the differential percentage rise in metabolism is 0.80 to 1.1 times as rapid as in body weight); the fourth segment has a slope of only about 0.2. The slope of the curves appears to vary directly with the percentage growth rate.

There is need for investigating the mechanisms behind these age changes; for correlating the age changes in metabolism with age changes in development of the oxidation-reduction enzymes⁶, with age changes in ability to derive energy by glycolysis or fermentation (as contrasted to respiration, see Ch. 6), with age changes in homeothermy (discussed in Ch. 11), and with structural changes (Ch. 17).

A most interesting report is that by Himwich *et al.*⁷ on age changes in tolerance to anoxia, hypoglycemia, fluoride, iodoacetate⁸, and carbon monoxide.⁹ While mature animals succumb in about three minutes, the average

survival values for newborn animals in a pure nitrogen atmosphere is, in minutes, 50 for rats, 25 for cats, 23 for dogs, 16 for rabbits, 7 for guinea pigs. The longer survival value for the newborn is attributed by Himwich to lower brain metabolism, to early poikilothermicity, which makes smaller demands on oxygen, and especially to the fact that younger animals can and do obtain more energy by glycolysis.² One may suggest that the less highly developed brain of the immature animal is less sensitive to oxygen lack than the more highly developed brain of the mature. Fig. 14.3, after Himwich⁷ *et al.*, illustrates the age changes in cerebral oxygen uptake and anoxic survival time in rats.

Fig. 14.3. Age changes in cerebral O₂ uptake and anoxic survival time in rats. From J. F. Fazekas, F. A. D. Alexander, and H. E. Himwich, *Am. J. Physiology*, **134**, 282 (1941).

14.3: Resting metabolism and pulmonary ventilation in dairy cattle.

The picture relating resting metabolism to surface area and to weight of cattle during postnatal growth is, in general, similar to that of rats (Figs. 14.1 and 14.2) with the exceptions that (1) since cattle are born at a more advanced stage of physiologic development, they do not show some of the early post-natal features observed in the age curve of rats (Ch. 16); and (2) the resting metabolism per unit area (or similar reference base) in cattle is above that of rats.

The measurements were made before the regular morning feeding, 8 to 12 hours after the previous evening feeding, by the oxygen-consumption method illustrated in Figs. 12.3 and 12.4. Unlike humans, cattle take some 48 hours to reach post-absorptive condition, more or less time depending on age

- and other factors. These data are not, therefore, “basal” metabolism, but normal, early-morning metabolism at rest in a comfortable recumbent position. The data thus represent approximately minimum energy cost of maintenance, presumably including the energy expense of the *work* of growth and also some of the heat increment of feeding (Ch. 4).

Our numerical data¹⁰ on the resting metabolism of Jersey and Holstein cattle are summarized in Tables 14.2 and 14.3. The resting metabolism *per square meter* per day is given in Figs. 14.4 and 14.5, and *total* resting metabolism as function of weight on logarithmic paper is given in Figs. 14.6 and 14.7.

Fig. 14.4a. Resting heat production, Cal/sq m/day as function of age in Jersey cattle. The surface area, sq m, was computed from the equation $A = 0.15W^{0.66}$ (see Fig. 13.2 for details).

The resting metabolism *per unit surface area* rises in cattle from 1300 to 1400 Cal/sqm/day shortly after birth to about 2100 Cal/sqm/day at about five or six months (weight near 100 kg) and remains at this level for the duration of observation, until 24 months. The resting metabolism following this age is confused in dairy cattle (as managed under commercial conditions; these animals were *bona fide* members of a commercial dairy herd and not “experimental animals”) by the heat increments of gestation and lactation.

The graph of the *total* metabolism as function of body weight on logarithmic paper, Figs. 14.6 and 14.7, shows a “break” at the age and weight correspond-

¹⁰ Brody, S., Kibler, H. H., and Ragsdale, A. C., Univ. Missouri Agr. Exp. Sta. Res. Bulls, 335 and 350, 1941-42.

Fig. 14.4b. The same metabolism data as in Fig. 14.4a plotted against body weight.

Fig. 14.5a. Similar data as in Fig. 14.4a but for Holstein cattle.

ing to maximum metabolism per unit area in Figs. 14.4 and 14.5, that is, at about five months or 100 kg. Unlike the rat age curve (Fig. 14.2), which shows three breaks, the cattle curve shows only the one break. The age curve of metabolism, as of growth (Ch. 16), of cattle is simpler than that of rats partly because cattle are born at a later developmental stage.

The equation $Y = aX^b$ was fitted by the method of least squares to each of the two segments. The heavy lines represent the equation, the light broken lines the standard error of estimate, designed by S_R , including between them two-thirds of the data. The light, broken lines III and IV represent

Fig. 14.5b. The same metabolism data as in Fig. 14.5a plotted against body weight.

the *basal* metabolism of *mature* animals of *different* species (mice to elephants), copied from Fig. 13.7.

Figs. 14.6 and 14.7 show that preceding the "break" at 5 to 6 months, or 200 to 300 lbs. live weight, the rise in resting maintenance energy cost is about 80 per cent of the rise in body weight (the value of the exponent b is 0.8); after the "break" the rise in metabolism is about 60 per cent of the rise in body weight (the value of b is 0.56 to 0.60), which is the same as the rise in surface area with increasing body weight (Fig. 13.2a and b : surface area = $0.15W^{0.58}$).

The consistency of distribution of the data is indicated by the high index of

Fig. 14.6. Jersey cattle. Resting oxygen consumption (left axis) and heat production in terms of Cal., Btu, and TDN (right axis), plotted against body weight. The heavy line represents the equation $Y = aX^b$ with the values of a and b given on the chart, as well as of $\pm SE$, which includes $\frac{1}{2}$ of the data. The lowest dash line—40% below the heavy line—represents the equation $Y = 70.5X^{.75}$ for basal metabolism (Cal./day vs. body weight in kg) of mature animals of different species.

Fig. 14.7. Similar data as in Fig. 14.6 but for Holstein cattle.

correlation and the low standard error of estimate. The consistency is indeed remarkable, considering that the measurements were taken at all seasons on many animals born at different months and years and measured by different persons and with different equipment.

The *resting* (not fasting or "basal") metabolism of the *growing* animals is seen to be considerably above that of the *basal* metabolism of *mature* animals of different species. As indicated at the bottom of Figs. 14.6 and 14.7, the basal metabolism of mature animals of different species is 40 to 48 per cent below that of the resting metabolism of the growing cattle, or the resting metabolism of the growing cattle is 70 to 90 per cent above that of the basal metabolism of mature animals of different species. The resting metabolism curve of growing rats shown in Fig. 14.2 is nearer the basal-metabolism curve for mature animals of different species than is that of the cattle. The fact that relatively mature cattle and perhaps other ruminants have a higher metabolism per unit area than other species is known.¹¹

Partly because of the interest in the ventilation problem by air-conditioning engineers, we have also collected data on the pulmonary *ventilation* (volume of air exhaled or inhaled per unit time) of these cattle. Such data are particularly useful for the light they throw on water vaporization, especially in slightly sweating or non-sweating animals, such as cattle. Although there is some question as to the saturation and temperature of the exhaled air, for practical purposes it is sufficient to assume that the exhaled air is saturated with moisture at the oral temperature of the species.¹² The pulmonary ventilation data, when combined with the oxygen-consumption data, thus furnish the ventilation or air-conditioning engineer practically all the needed data: air exhalation, oxygen consumption, carbon dioxide exhalation (virtually equivalent by volume to oxygen consumption) and water vaporization from the respiratory-oral system, which in non-sweating species is near the total water vaporized.

The ventilation rate tends to vary with the metabolic (oxygen-consumption) rate. In slightly sweating or panting animals such as cattle, the pulmonary ventilation rate serves a dual purpose, supplying oxygen and removing carbon dioxide and also fanning the pulmonary-oral surfaces, thus accelerating vaporization from these surfaces. In such species, therefore, the ventilation rate varies with temperature as well as with metabolic rate, and it is not surprising to find that the variability of the ventilation data is twice that of the metabolism data, as indicated in Figs. 14.8 and 14.9, representing on logarithmic paper ventilation rate as a function of live weight.

¹¹ Ritzman, E. G., and Benedict, F. G., "Nutritional physiology of the adult ruminant," Carnegie Inst. Washington Pub., 494, 1938.

¹² The literature indicates that at the point of exhalation the air is 2° to 3° C below that of the mouth, and about 90 per cent saturated with respect to this exhalation temperature. In man, the usual oral temperature is assumed to be 37° C, the air at expiration 34° to 36° C, and the water content of the expired air is about 80 per cent of that of saturated air at 37° C, containing 0.032 to 0.037 g. H₂O per liter expired air. See Newburgh, L. H., and Johnston, M. W., *Physiol. Rev.*, **22**, 1 (1942).

Because of the high variability of ventilation data, no attempt was made to analyze the curve in two segments, and the equation $Y = aX^b$ was "forced" on the data by the method of least squares. The slope, b , of the resulting curve is seen in Figs. 14.8 and 14.9 to be 0.72 for the Jersey cattle and 0.77 for the Holstein cattle, which are reasonable values.

A surprising feature of Tables 14.2 and 14.3 is the low oxygen decrement in the expired air, about 2 per cent, much below that in man. Direct

Fig. 14.8. Pulmonary ventilation rate (volume of air expired or inspired per minute) plotted against body weight. The heavy line represents the fitted equation $Y = aX^b$, the dash lines, the standard error of estimate, S_R .

analysis of expired air (the values in Tables 14.2 and 14.3 are computed from the ventilation rate and from oxygen consumption) yields higher values; in one analysis on a six-year old Guernsey cow the results were 2.4 per cent oxygen deficit immediately after feeding and 2.2 per cent after a 48-hour fast. The use of the oxygen-spirometer method reduces the apparent oxygen deficit in expired air¹³, but not enough to explain the low value for the oxygen deficit. Carpenter¹⁴ suggested that in these (slightly sweating or non-sweating)

¹³ Carpenter, T. M., *Boston Med. and Surg. J.*, **181**, 334 (1919), reported a ventilation rate (for man) of 6.32 liters per minute for closed-circuit apparatus and 5.38 liters per minute for open-circuit.

¹⁴ Personal communication.

animals "the water elimination from the skin is so low that in order for the heat to be eliminated by way of vaporization of water there has to be a tremendous increase in lung ventilation" with consequent decrease in oxygen deficit in the expired air. We also have good data indicating that the larger the animal, the lower the ratio of oxygen to consumed air inhaled.

It is interesting to compare, by way of conclusion, the metabolism of the small Jersey and larger Holstein. This is done in Fig. 14.10. After the age of about six months Holstein heifers have a resting metabolism of, on the

Fig. 14.9. Ventilation rate as in Fig. 14.8 but for Holstein cattle.

average, 2140 Cal/sqm/day; Jersey heifers, 2000 Cal/sqm/day. While these breed differences are relatively slight, they are statistically significant. The higher metabolism per unit surface area of the Holsteins *at given ages* (lower left chart) may be due to their more rapid growth rate. There is considerable evidence indicating that the heat production increases with increasing growth rate (Ch. 3).

When plotted against *body weight*, on the other hand, the metabolism per unit surface area and per animal appears to be greater in the Jerseys prior to about 100 kg body weight (lower-right and upper-left curves). This may be due to the fact that at a given body weight the Jersey is physiologically older

than the Holstein, and, as indicated in the charts, the metabolism per unit surface area (and per animal) rises with increasing age up to about six months, or up to about 100 kg body weight.

The higher Holstein ventilation rate at given body weights (upper-right curve) may perhaps be explained by the higher Holstein heat production (lower-right curve): ventilation rate is adjusted not only to the need for oxygen but also to the need for heat dissipation, since ventilation is an important method of heat dissipation in cattle and other non-sweating animals.

Fig. 14.10. Comparison of metabolic and ventilation rates in Jersey and Holstein cattle.

To summarize: the resting metabolism per unit area in dairy cattle rises from birth to puberty and remains roughly constant until the age of 24 months. The general age picture of metabolism per unit area is not unlike that for rats, but the changes are less extensive because of the more advanced physiologic age of cattle at birth. When total metabolism is plotted against weight on logarithmic paper the slope of the curve is about 0.8 prior to the break at 5 to 6 months, and 0.56 to 0.60 after this age, which means that following six months the metabolism per unit area is practically constant. The resting metabolism of growing cattle per unit area is considerably above that of

growing rats or man. The ventilation rate of growing cattle increases with approximately the 0.7 power of body weight.

14.4: Resting metabolism in goats. Goats tend to be seasonal breeders, usually conceiving in October or November (the gestation period is 151 days). Goats are, moreover, very sensitive to changes in temperature, pasture, and other conditions associated with changes in season, all of which are reflected in the metabolic rate (Fig. 8.12a). The births of the 22 goats we investigated¹⁵ were distributed throughout the year, with consequent individual differences in the slope due to seasonal and related influences. The slope relating resting metabolism to body weight ranged from 0.51 to 1.0.

Because of this variability no attempt was made to analyze the goat data with respect to the presence of segments as was done for rats and cattle. The equation $Y = aX^b$ was simply "forced" on the data by the method of least squares giving slopes (values of the exponent b) ranging from 0.50 to 0.72. It may be recalled that after the age of six months the slope of the curve for cattle is 0.60 (Figs. 14.6 and 14.7), quite close to the average of 0.64 for the goats.

The slope for all the females was 0.64; for all the males, 0.68; for all the Toggenberg goats (males and females), 0.67; for all the Angoras (males and females), 0.56.

We did not measure the surface area of the goats and found no surface-area data in the literature; therefore, no charts relating metabolism to surface area are given.

The metabolism for given individuals may be estimated from the following prediction values or from the equations.

Body Wt. (lbs)	Body Wt. (kg)	Resting metabolism (Cal/day)	Body Wt. (lbs)	Body Wt. (kg)	Resting metabolism (Cal/day)
4	1.8	240	45	20.4	1136
6	2.7	312	50	22.7	1215
8	3.5	375	60	27.2	1366
10	4.5	432	70	31.8	1508
12	5.4	486	80	36.3	1643
14	6.4	537	90	40.8	1772
16	7.2	585	100	45.4	1896
18	8.2	631	110	49.9	2016
20	9.1	675	120	54.4	2132
25	11.3	779	130	59.0	2244
30	13.6	875	140	63.5	2353
35	15.9	967	150	68.0	2460
40	18.1	1053	154	70.0	2502

Breed	Equation
Toggenberg males	Cal. = $88.5 \text{ lb}^{0.710}$ or $155 \text{ kg}^{0.710}$
Toggenberg females	Cal. = $88.8 \text{ lb}^{0.663}$ or $150 \text{ kg}^{0.663}$
Angora males	Cal. = $120 \text{ lb}^{0.506}$ or $192 \text{ kg}^{0.506}$
Angora females	Cal. = $140 \text{ lb}^{0.504}$ or $209 \text{ kg}^{0.504}$

¹⁵ Mo. Agr. Exp. Sta. Res. Bull. 291, 1938.

The estimates here given for the *resting* metabolism of *growing* goats are considerably above the *basal* metabolism values published by Benedict *et al.*¹⁶ for more mature animals.

14.5: Resting metabolism and pulmonary ventilation in horses. It was more difficult to get young horses than cattle to rest during the metabolism measurements. This may explain the differences in distribution between

Fig. 14.11. Comparison of resting metabolism and pulmonary ventilation in horses and cattle.

the horse and cattle data, especially when plotted in terms of metabolism per unit area as function of age or weight, shown in Fig. 14.11.

The data on the Shetland ponies, Fig. 14.12, are too few to indicate the presence of breaks, if any, in the curve. The slope of the general trend, 0.52 to 0.59, is relatively low (in cattle the slopes were about 0.8 before six months and 0.6 after six months).

¹⁶ Benedict, F. G., "Vital Energetics," Carnegie Inst. Washington Pub. 503, 1938. Ritzman, E. G., Washburn, L. E., and Benedict, F. G., "The basal metabolism of the goat," New Hampshire Agr. Exp. Sta. Tech. Bull. 66, 1936.

Fig. 14.12. Resting metabolism of ponies as function of body weight on logarithmic paper. Left axis oxygen consumption; right axis oxygen equivalents in Calories, Btu and TDN per day. The upper axes represent approximate ages in months.

Fig. 14.13. Same as Fig. 14.12 but for Percheron horses and carried to more advanced ages.

Note especially in Fig. 14.12 that the metabolism in horses while standing is the same as while lying. Cattle, sheep, and men, on the other hand, expend about 10 per cent more energy standing than lying (Ch. 24). This observation that (unlike cattle, sheep, and men) horses have no extra energy expense for standing is not surprising since, unlike cattle, horses are equipped with very powerful suspensory and check ligaments which enable them to rest as comfortably in a standing as in a lying position. Indeed, horses

Fig. 14.14. Ventilation rate as function of body weight (and age, upper axis) of the Percheron horses.

usually sleep while standing. Winchester¹⁷ measured the relative oxygen consumption of these two ponies in standing and lying positions (independently of the measurements represented in Fig. 14.12), confirming the results in Fig. 14.12.

Fig. 14.13 for the (large) Percheron horses shows a sharp change in slope, from 0.5 to 1.0, at an age of approximately two years (the pony data extend

¹⁷ Winchester, C. F., "The energy cost of standing in horses," *Science*, **97**, 24 (1943).

to only two years, while the Percheron data extend to 5 years). This rise is independent of sex, since castrated animals (geldings) exhibit the same rise as normal females. This slope difference is probably due to ever-increasing physical exertion. These animals were hard-working farm horses. (It is

Fig. 14.15. Metabolism of children as function of body weight on logarithmic grid. For sources of data and further details see Fig. 14.16a and b.

generally known that the basal or resting metabolism of active athletes is higher than of sedentary individuals of the same weight.) Not all the horses worked equally hard, or were equally muscular, which explains the rather wide scattering of the data.

The distribution and slope of the ventilation data for the horses, Fig. 14.14, is similar to those for cattle (Figs. 14.8 and 14.9).

As previously noted, Fig. 14.11 is a comparison of the horse and cattle data. Instead of rising, as for cattle, the metabolism per unit area declines in horses during the first few months, perhaps because of the greater restlessness of the young colts. Better data are likely to show a rise in metabolism per unit area as in cattle. For given weights horses have a higher metabolism than cattle.

The numerical data for horses are summarized in Table 14.4.

Fig. 14.16a. The same data as in Fig. 14.15 but plotted separately for males (a) and females (b), and the metabolism for various levels given for convenient comparison.

14.6: Metabolism in man. We shall not discuss the age changes in metabolism per unit area in man since this is discussed in detail in Du Bois' book and in less detail in physiology textbooks. Our remarks are confined to metabolism of the growing man of average build as a function of weight when plotted on a logarithmic grid, illustrated in Fig. 14.15, which brings out the following features.

(1) There is a change in slope in the metabolism-weight curve at approximately three years of age ("natural weaning" age?), corresponding apparently to the break at three weeks (weaning age) in rats and five months (weaning age) in cattle. This "break" corresponds to maximal metabolism per unit area (see the Du Bois insert in Fig. 14.4a).

(2) From birth to three years, the metabolism varies directly with body weight; the slope of the curve is 1.0. Extrapolating the equation to intra-uterine growth gives zero metabolism at zero weight, indicating the possibility that this postnatal metabolism equation also represents prenatal metabolism. While, as previously explained, it would be impossible for the metabolism *per unit surface area* to be the same in early prenatal as during postnatal life, the metabolism could well be the same *per unit weight*, 50 Cal/kg/day, as indicated by the equation $Y = 50X^{1.05}$ (Fig. 14.15). There is no significant sex difference in metabolism before three years.

Fig. 14.16b. See legend of Fig. 14.16a.

(3) Between the ages of 3 and 16 years the slope of the curve is not 1.0, as it was before 3 years, but about 0.6 (near the value for cattle, goats, and horses previously discussed). The slope is 0.59 for boys and 0.64 for girls, and boys tend to have the higher metabolism.

(4) Between 16 and 31 years, the slope tends to be higher for men than for women, 0.65 for men and 0.46 for women.

(5) Sex differences disappear after 60 years.

The light, broken curve in Fig. 14.15 represents the metabolism of mature

animals of different species (Fig. 13.7). On maturing, the metabolism of man approaches that of the general curve relating metabolism to weight in mature animals of other species.

Fig. 14.17. The relation between the heat increment of gestation, Q , and birth weight, M , plotted on a logarithmic grid. The broken curve and solid circles represent the ratios of the heat increments of gestation, to birth weight of young; the continuous heavy curve and crosses represent the total heat increment of gestation plotted against birth weight.

Figs. 14.16a and b represent the same data as Fig. 14.15, but show how the metabolic level tends to drop for given body weights at successive age intervals (#3, 16 to 30 years; #4, 30 to 60 years; #5 over 60 years). Other aspects

of metabolism during aging, especially the oxygen consumption per pulse per unit weight, are discussed in Chapter 18.

Some may prefer the results in numerical form given in Table 14.5. This table shows the total metabolism in Cal/day and also per kg, per lb, and per sq meter for various age intervals and body weights. The metabolism energy is here also expressed in terms of milk energy. Thus, a 14-kg or 31-lb infant expends as much energy for resting maintenance per 24 hours as is given off on burning in a bomb calorimeter approximately a quart, or liter, of milk containing 4 per cent fat. This does not mean that a quart of milk is all the energy that a 14-kg infant needs, since there is a variable energy expense in

Fig. 14.18. Metabolism as function of fetal weight of sheep on a logarithmic grid; also blood volume as function of fetal weight and fetal plus placental weight.

utilization of the milk and the infant also needs food for growth and for various activities above that of resting maintenance.

14.7: Prenatal heat production in relation to birth weight. We measured¹⁸ the heat increment of gestation (the extra heat production of resting animals during gestation above the non-gestating level) of rats, cattle, horses, sheep, and swine. As it was unfortunately necessary to confine the measurements to young primipara, the heat and weight increments of gestation were complicated by the growth of the mother. It may nevertheless be instructive to correlate the heat increment of gestation with the birth weight of the young.

¹⁸ Brody, S., Mo. Agr. Exp. Sta. Res. Bull. 283, 1938.

This heat increment of gestation, of course, includes not only the total of the "basal" or "resting" metabolism of the embryo and fetus from conception to birth but also that of the involved accessory structures and of the maternal body, whose heat production is accelerated during gestation by increased endocrine activity.

The result of the correlation between the heat increment of gestation and birth weight is shown in Fig. 14.17 (plotted from Table 14.6) and is given by the equation $Q = 4400M^{1.2}$ in which Q is the total heat increment in Calories and M is birth weight in kilograms. The heat increment of the incubating chick is included in the chart, but not in fitting the equation to the data.

This equation means that the production of a 1-kg young is associated with a heat increment of gestation of 4400 Cal. The heat increment per kg young necessarily varies with the time required to develop it. This is probably the meaning of the exponent 1.2: increasing the birth weight 100 per cent (and therefore increasing the time of prenatal growth) tends to be associated with an increase in heat production of 120 per cent. The longer the prenatal growth period, the greater the prenatal maintenance cost per unit young, and also for the accessories and mother's heat increment of gestation. Yet the data on slow-growing man (by Root and Root and by Sandiford and Wheeler) fall right on the line. Rabbit and most rat data, however, fall below the line.

The regularity of distribution of the data in Fig. 14.17 tempts one to say that the given equation represents a "law" of constant gestation energy analogous to Rubner's "law" of constant growth energy (Ch. 3), which states that the construction cost of body substance during the first prenatal doubling of body weight is 4800 Calories per kilo (except for man). While the two constants, 4400 Calories in Fig. 14.17 and 4800 of Rubner, appear similar, they evidently reflect different situations: Rubner's value refers to the energy cost of postnatal growth of the individual, including the stored energy, whereas the 4400-Cal value in Fig. 14.17 refers to the heat increment of gestation, including the heat increments of all accessory structures and of the mother, but not including the stored energy. Moreover, Rubner's "law" assumes a linear relation (the exponent is 1.0) whereas the equation in Fig. 14.17 indicates an exponent of 1.2.

The gestation heat increment thus includes (1) the energy expense of maintenance of the pregnant uterus; (2) "work" of growth; (3) increased work of the maternal organism (increased circulatory, respiratory and excretory activities); (4) endocrine influences on metabolism of the mother. Even in the incubating chick there may be an extra heat production by the allantois, yolk sack, and even an extra heat production associated with the presence of the yolk¹⁹; and the situation is still more complex in mammals. The problem

¹⁹ Barott, H. G., Byerly, T. C., and Pringle, E. M., "Effect of removal of unabsorbed yolk on heat production of chicks," *J. Nut.*, **11**, 191 (1936). Barott, "Effect of temperature and other factors on energy metabolism of chick embryos," U. S. Dept. Agr. Tech. Bull. 553, 1937.

of prenatal growth has been adequately discussed by Needham⁶. The following notes review briefly the literature as it bears particularly on the above discussions.

Fig. 14.19. The metabolism of the chick embryo as function of body weight on a logarithmic grid.

According to Barcroft²⁰, the embryo is under no necessity to maintain its own body temperature; it has no surface, if the word "surface" be used in the physiological sense, as an area from which heat is dissipated. There seems little point, therefore, in calculating the relation of heat production or blood volume to the cutaneous area. The blood volume is more reasonably represented as a percentage of weight of the actual embryo or as a percentage of the embryo plus the placenta, through which circulation takes place, and which may therefore be regarded as an integral part of the fetus.

²⁰ Barcroft, J., *Physiol. Rev.*, **16**, 103 (1936).

Barcroft measured the oxygen consumption and blood volume of the fetal sheep and goat. We have computed the power function relating oxygen consumption and blood volume to body weight with the result shown in Fig. 14.18. The fetal oxygen consumption is seen to increase directly with simple body weight ($W^{1.0}$). The equation given in Fig. 14.18 is

$$Y = 0.015X_2^{1.0}$$

meaning that the heat production per unit weight is approximately constant, 0.015 Cal/g/day or 15 Cal/kg/day, a comparatively low value, numerically equal to the basal metab-

Fig. 14.20a. Changing body weight with advancing gestation and lactation in dairy cattle. Plotted by us from data by R. F. Morgan and H. P. Davis, Univ. Neb. Agr. Exp. Sta. Res. Bull. 82, 1936.

olism per kilo per day of mature cattle or horses. (The metabolism per square meter as computed by us is between 200 and 600 Cal per day.) The blood volume in the fetal goat increases with the 0.79 power of fetal weight and with the 1.0 power of the combined weight of the fetus and placenta. These results substantiate our suggestion that early metabolism varies not with surface area but with simple weight, and contradict Rubner's assumption that it varies with surface area.

The metabolism of the chick embryo also varies more nearly with simple weight ($W^{1.0}$) than with surface area. This is shown in Fig. 14.19, plotted from the indicated sources. By weight we mean wet weight. When metabolism is plotted against dry weight (curve 3, Fig. 14.19), the slope ranges from 1.2 to 0.53, depending on the developmental stage.

Fig. 14.20b. Changing body weight (right axis) and metabolism (left axis) with advancing gestation and lactation in the rat during first, second, third, and fourth pregnancies.

Several other references may be cited. Murlin²¹ reported on the pregnancy metabolism of a dog. Her heat production during sex rest was 505 Cal; 3 days before giving birth to 1 puppy, 551 Cal; 3 days before giving birth to 5 puppies, 765 Cal. In other words, the gestation metabolism above sex rest was 46 Cal for 1 puppy, and about 5 times (5.6 times) that much, 260 Cal, for 5 puppies. Pommerenke, Haney and Meek²² investigated the energy metabolism of gestation and lactation in rabbits which confirm Murlin's results on the dog.

Carpenter and Murlin²³ reported that the maternal organism and fetus function as two separate units in their energy consumption; because the metabolism of a pregnant mother shortly before parturition was nearly the same as mother *and* child after child-birth. Sandiford and Wheeler²⁴ came to a similar conclusion, but on the basis of surface-area computations which were criticized by Rowe and Boyd²⁵.

Fig. 14.20c. The course of changing activity and food intake with advancing gestation and lactation in the rat. From Ging H. Wang, *Am. J. Physiol.*, 1925, p. 736.

Schwarz and Drabkin²⁶, and others, attributed increased heat production during gestation to increased thyroid activity. This conclusion is based in part on the rise in blood iodine from the second (15.5 gamma per cent) to the tenth lunar month (22.5 gamma per cent) and its decrease during the first two weeks of puerperium; in part on the hypertrophy of the anterior pituitary, which presumably increases in its thyrotropic activity during pregnancy; and in part on hypertrophy of the thyroid during pregnancy.

Root²⁷ reported data on basal metabolism of a primipara in whom pregnancy was uncomplicated by gain in adipose tissue or disease. The basal metabolic rate during the

fourth month was essentially that predicted by the standard for non-pregnant women of the same age, height and weight, then followed by a steady increase until eleven days before delivery, when the total basal metabolism was 23 per cent above that during the

Fig. 14.21a. Influence of reproductive condition on growth and reproduction of white rats. From R. Bogart, G. Sperling, L. L. Barnes, and S. A. Asdell, *Am. J. Physiol.*, **124**, p. 362 (1940) and from Asdell, Bogart and Sperling, Cornell Univ. Memoir 238, 1941, p. 6.

Fig. 14.21b. See legend of Fig. 14.21a.

fourth month—an increase out of proportion to the standard prediction tables for normal women, with corresponding gain in weight. The Cal/kg gain in basal metabolism from the fourth month of pregnancy to the eleventh day before delivery was 7.6 per cent. Following delivery, although the subject's weight remained nearly stationary, the basal

metabolism fell to 9.6 per cent below the rate observed during the fourth month of pregnancy. "The high metabolic rate during the last month of pregnancy only partially reflects the much higher metabolic rate of the fetus per unit of weight, since the maternal weight is made up in part of inactive tissues such as edema and the fluid contained in the amnion. It appears that the metabolism of the fetus at term was approximately 37 Cal/kg, whereas the basal metabolism of the mother was 23.5 Cal/kg during the fourth month of pregnancy and 22.1 Cal/kg one month after delivery".

A report²⁸ on basal energy and mineral metabolism on a young primipara for 66 days ante-partum concludes thus: "The rise in metabolism throughout the latter part of pregnancy parallels the cumulative nitrogen and sulphur curves. It is felt that a hormone influence responsible for the synthesis of the new mass of protoplasm must likewise be included in any explanation of the phenomenon".

Fig. 14.22a. Age course of growth in weight (right) and of heat production (left) of the chick. The area under the curve is the total heat production, or heat increment of incubation, is seen to be 19.04 Cal.

Several reports point to a decline in metabolism in the early stages of pregnancy²⁹, perhaps due to decline in muscular activity. Data on rats by Wang³⁰ show a drop in activity from 16352 drum revolutions (in an exercising cage) preceding conception to 2779 revolutions following conception. Slonaker's³¹ data show a similar decline: "I have found that both during gestation and pseudopregnancy there is great reduction in activity accompanied by little change in food consumption. The energy which is usually used for activity is then used for growth".

While the weight gains during pregnancy are considerable (Fig. 14.20 to 14.23), the food consumption is not increased proportionately because the energy saved by decreased muscular activity during pregnancy is used for the growth. Wang quotes Schick's observation that humans instinctively refrain from bodily activity during pregnancy, and this energy saving is used for meeting the increased demand for nourishment. Data by Macy and co-workers³² on food consumption of human mothers demon-

strate this fact. Eckles²² reported that pregnancy in dairy cattle, leading to a 16 per cent increase in body weight (Fig. 14.20a), does not involve an increase in feed consumption. The 16 per cent weight increase during pregnancy includes relatively

Fig. 14.22b. Heat increments of gestation of rats and horses; these are represented by the areas between the curve of heat production and the base line assumed to represent the heat production of the animals if they were not pregnant. The weight increments of gestation are likewise shown graphically.

Fig. 14.22c. Similar data as in Fig. 14.22b but for horses.

little energy: about 75% of the weight of a new-born calf is water; 85 per cent of the placenta is water; 95 per cent of the amniotic fluid is water; only 15 to 25 lbs of the new-born calf is dry matter (equivalent to about 200 lbs average milk):

While Eckles' cows made normal pregnancy gains on a maintenance ration, Cole and Hart³⁴ observed increased food consumption in rats by the second day after conception, and that pregnancy stimulates the appetite and growth of rats beyond that of non-bred litter-mate controls (Fig. 7.4). They postulated that pregnancy stimulates the anterior pituitary to secrete one or more hormones involved in increasing appetite. The excess gains made by the pregnant rats remain fairly constant for the first six pregnancies, after which further pregnancies have less effect. The excess gains are made, for the most part, during pregnancy, although rats suckling four to six young continue to gain as rapidly as non-bred controls.

Mumford first observed at the Missouri Experiment Station³⁵ that early breeding of sows does not reduce their ultimate size and that delaying breeding reduces the ultimate body size as indicated by the following summary:

Age of breeding of sows (days)	Mature weight of sows (lbs)	Total litter weight at birth
218	415	20.0
479	401	19.9
838	384	14.9

Slonaker³⁶ first observed this effect on rats, confirmed by Cole and Hart, and by Bogart *et al.*³⁷, who observed that breeding rats grow more rapidly and for a longer time than non-breeding. It is the heavy lactation that constitutes the drain on the mother not the gestation. Bogart attributes the more rapid growth of breeding rats not to the growth-stimulating effect of gestation as such, but to the removal by the corpus luteum of the growth-inhibiting effect of estrogens. This is substantiated by the growth-stimulating effect of pseudopregnancy.³⁸ Ovariectomy has a similar growth-stimulating effect by eliminating the growth-retarding estrogenic influences³⁷ (Sect. 7.2.1).

Reproduction (the gestation not lactation part of reproduction) not only stimulates the growth of the maternal organism but it also stimulates further reproduction. Reproduction stimulates further reproduction because³⁹ "breeding promotes a greater

Fig. 14.23a. Heat and weight increments of gestation of cattle.

harmony between the ovaries and other glands of internal secretion". The conclusions of the Asdell group are illustrated graphically in Fig. 14.21a and b.

Fig. 14.23c. Heat and weight increments of gestation of goats.

Fig. 14.23b. Heat and weight increments of gestation of cattle.

14.8: Estimating the heat increment of gestation and total prenatal heat production. Fig. 14.17, representing the relation between birth weight and the heat increment of gestation, is necessarily crude because of the indirect method of estimating the heat increment of gestation and because of its mixed significance.

Fig. 14.23d. Heat and weight increments of gestation of does.

The simplest situation is that of the heat increment of incubation of the bird embryo. Here the total heat production, that is, the heat increment of incubation, is virtually the heat production of the bird embryo. This heat increment is shown (Fig. 14.22a) to be approximately 20 Cal for the chick embryo of the domestic fowl: about 20 Cal heat is dissipated during the production of a 40-Cal chick-embryo tissue. These 20 Cal represent the energy

cost of maintenance of the formed embryo (Ch. 3) and perhaps of the "work" of growth. This is simple.

The situation is much more complex for intrauterine growth of mammals. The embryo, or fetus, is a small part of the mother whose metabolism is measured. As previously explained, the maternal organism undergoes profound metabolic changes involving the metabolism-stimulating endocrines during gestation, so that the heat increment of gestation is by no means the heat production of the embryo and fetus. The situation is further complicated if the mother is young and is growing herself. Yet Figs. 14.22b and c and 14.23 are based on just such data on the heat increments of gestation of young primipara.

The method of obtaining the heat increment of gestation is illustrated in these figures. The time curves for metabolism and for weights of the non-

Fig. 14.24a. Demonstrates on semi-log paper the parallelism of the apparent endogenous nitrogen excretion and basal metabolism in rats of different body weight.

gestating animals are extrapolated by straight lines to the weight and metabolism of the animals shortly after parturition, and the areas between the extrapolated lines and the observed lines for metabolism represent the heat increments of gestation. It is these heat increments of gestation that are given in Table 14.6.

In spite of the crudeness of estimating the heat increment of gestation and their confused significance, the distribution of the data in Fig. 14.17 is quite orderly, and is apparently satisfactory for a first estimate relating prenatal heat production to birth weight.

In this connection the prenatal age curves of growth in weight (Figs. 14.23b and 14.23d) have some inherent interest. The values of k , the slopes of the

curves, represent the instantaneous relative growth rate per day. Thus when the value of k is 0.16, the instantaneous growth rate is 16 per cent per day (Ch. 16).

When the heat increment of gestation is represented in terms of Cal/kg/day or Cal/sqm/day the resulting ratios are, as might be expected, unreasonably high (cf. Barcroft's direct measurements plotted in Fig. 14.18), since we measured not the heat production of the embryo or fetus but the heat increment of gestation, of which the heat production of the young is only one component.

Fig. 14.24b. The apparent endogenous nitrogen excretion in rats varies with the $1.00 - .274 = 0.726$ power of body weight.

14.9: Endogenous nitrogen excretion during growth. As previously explained (Ch. 13), the ratio of endogenous nitrogen to basal metabolism in *mature animals of different species* is approximately constant, 2 mg N/Cal; and the endogenous nitrogen, like basal metabolism, increases with approximately the 0.7 power of body weight. What is the relation between endogenous nitrogen and basal metabolism during growth? The writer believes that,

following the age of natural weaning, they both tend to vary with 0.5 to 0.6 power of the body weight and that the ratio N/Cal is approximately constant. However, one cannot be certain for several reasons, one being that the basal metabolism and endogenous nitrogen concepts do not have the same significance in rapidly growing as in mature animals. One can only speak of *apparent* endogenous and basal metabolism. It is evidently difficult to attain

Fig. 14.24c. The apparent endogenous nitrogen excretion seems in this case to vary with the 0.42 power of body weight in growing Holstein cattle. Chart by Eric Swanson and H. A. Herman.⁴²

an endogenous nitrogen level without disturbing normal growth. Moreover, the apparent endogenous level is influenced by many factors⁴⁰: dietary protein level and quality before and during the period of specific nitrogen starvation, age, and so on, as indicated by Figs. 13.19, 14.24, and 14.25.

Other conditions being equal, the lowest (endogenous) nitrogen excretion is attained not on a "protein-free" diet (0.5 mg N/gram air-dried food), but on one containing 5 to 6 mg N in the form of egg yolk per gram air-dried food (Mitchell).

⁴⁰ Ashworth, U. S., and Brody, S., Mo. Agr. Exp. Sta. Res. Bulls., 189, 190, 1933. Ashworth, *Id.*, 223, 228, 1935. Mitchell, H. H., and Hamilton, "The biochemistry of amino acids," New York, 1929. Smuts, D. B., *J. Nut.*, 9, 403 (1935).

The nitrogen excretion on a N-poor diet often continues to decline for 60 days^{40,41}. Employing such techniques, the ratio of the *apparent* endogenous

Fig. 14.25a. Influence of protein level (prior to the specific nitrogen inanition diet) on the course of nitrogen excretion.

nitrogen to the *apparent* basal metabolism in young rats may be reduced to 1.5 or even to 1.0 mg N per Cal heat production. Such dietaries, of course, disturb the growth process.

⁴¹ Deuel, H. J., Sandiford, I. and K., and Boothby, W. M., *J. Biol. Chem.*, **76**, 391 (1928); Smith, M., *Id.*, **68**, 15 (1925). Ashworth and Brody,⁴⁰

The above discussion makes it evident that it is a technically difficult problem to obtain data on endogenous nitrogen in normally growing animals. Nevertheless, the closeness of correlation between basal energy and endogenous nitrogen seems unmistakable. The following illustrate the above discussion.

Fig. 14.25b. Influence of body weight (age) on the course of nitrogen excretion—on the time required to attain the apparent endogenous level.

Fig. 14.24a shows the 'parallelism' of "basal" energy metabolism and endogenous nitrogen excretion (plotted on arithlog grid) of rats. Fig. 14.24b shows that the endogenous *N* excretion per unit weight declines with $M^{-0.274}$

or increases with $M^{0.726}$ (M is used in the chart to represent body weight instead of the usual W). This value of the slope is unexpectedly high for growing animals; it is close to that for mature animals of different species (Fig. 13.14).

Fig. 14.24c, shows⁴² (on a log-log grid) that the endogenous nitrogen in growing Holstein heifers increases with only the 0.42 power of body weight, an unexpectedly low value.

Fig. 14.26. Basal metabolism per unit weight, Q/W , of humans as function of body weight during growth. The heavy curve represents the given equation, the broken curves represent 10 and 20 per cent deviations from the average. 75 per cent of the data fall within ± 10 per cent of the average curve, and 99.5 per cent of the data fall within ± 20 per cent of the average curve. The data points are based on reports by Benedict, F. G., *Am. J. Physiol.*, **85**, 607 (1928), Benedict and Talbot, F. B., Carnegie Inst. Washington, Pub. 302 (1921), Harris, J. A., and Benedict, Id., Pub. 279, 1919, Boothby, W. M., and Sandiford, I., *J. Biol. Chem.*, **54**, 791 (1922).

The difference in slope for the growing cattle and rats is probably due to differences in experimental treatment, because as previously noted, the

⁴² Swanson, Eric, and Herman, H. A., Mo. Agr. Exp. Sta. Res. Bull. 382, 1943.

apparently endogenous nitrogen is sensitive to many factors, any one of which may affect the result. This is especially true of cattle with the rapid age changes in the digestive system and character of diet consumed. The writer feels that 0.4 is too low for the slope and that it will ultimately be shown to be nearer 0.6 (as for resting metabolism).

Figs. 14.25a and b show how the excretion of total N, N per unit body weight, and body weight vary with time on the low N diet, and the influence of protein level before the fast, and of body weight, on the shape and level of the N-excretion curves. The problem of the relation of endogenous nitrogen to body weight during growth is by no means solved, but we have here a be-

Fig. 14.27. Comparison of metabolism per unit surface area for swine and dairy cattle plotted against age.

ginning indicating that endogenous N and basal metabolism during growth both follow the same course, *i.e.*, that as a general rule both tend to increase with approximately the 0.6 power of body weight as contrasted to the 0.7 power of body weight for mature animals of different species.

14.10: Metabolism per unit weight as function of weight and of age during rapid growth. The preceding analysis of metabolism was concerned with surface area or with W^b as reference base. We found that the numerical value of b , when using W^b as base, is approximately 0.7 for mature animals of different species and approximately 0.6 for the same animals when growing.

In addition we employed⁴³ simple weight, $W^{1.0}$, or m , as reference base in the form of the relation

$$Q/m = ae^{-kt} + c$$

or

$$Q/m = ae^{-km} + c$$

in which Q is heat production for body weight m and age t ; k is the relative (or percentage when multiplied by 100) decline in Q/m with increasing age, t , or weight, m ; a and c are constants, c being the asymptote which Q/m approaches as a limit. The constant c may be dropped for a short segment of the $Q/m - m$ or $Q/m - t$ curve. These equations, of course, say that the heat production per unit body weight declines exponentially (Chs. 5, 16) with increasing age or weight.

Fig. 14.28. Resting metabolism per unit surface area as function of age in Rhode Island Red chickens. (Surface area was computed from the equation, surface area in sq. cm. = $8.19 \times (\text{body weight in gms})^{0.705}$.) The resting metabolism was computed on the assumption that 1 liter of oxygen had a heat equivalent of 4.9 Cal.

An application of the above equations to Q/m values during growth is presented in Fig. 14.26, and prediction values based on such analysis are given in Table 14.7 and those following it. Figs. 18.7 and 18.8 (Ch. 18), illustrate the life curves of the Q/m ratios. The Q/m ratio is there seen to rise post-natally until full homeothermy is attained, and declines thereafter to c as limiting value, except for a brief and relatively slight flare-up during puberty.

14.11: Summary and conclusions. While the ratio of metabolism per unit surface area, or much more precisely per W^b , is approximately constant for mature animals of different homeotherms (Ch. 13), this is not the case for the

⁴³ Mo. Agr. Exp. Sta. Res. Bulls. 166 and 176, 1937.

same animals when growing. During growth the metabolism per unit area, or per W^b , shows a peak; and when the total metabolism is plotted against weight on a log-log grid, the curve shows a "break". Prior to this peak or break, the metabolism tends to be directly proportional to simple weight, $W^{1.0}$; thereafter to $W^{0.6}$ or, roughly, to surface area.

This metabolic peak or break raises questions concerning its meaning. Is it associated with puberty? weaning? change in growth rate? stabilization of the neuroendocrine-homeothermic system? An inspection of the position of the metabolic peak in different species shows many variations in relation to weaning and puberty. For instance, the peak coincides with both puberty and weaning in cattle (puberty and weaning coincide in cattle); it occurs in swine⁴⁴ at puberty (at 7 months, Fig. 14.27) but not at weaning (which occurs at approximately 2 months of age); it occurs in rats sometime between weaning and puberty (Fig. 14.1); it coincides in humans with weaning (2 to 3 years, prior to which age milk is an indispensable part of the diet) although a relatively insignificant pubertal peak (near age 13 years) has also been reported⁴⁵; in chickens (Fig. 14.28) the metabolic peak occurs at the age of about one month^{46, 47} while puberty occurs at, perhaps, 5 or 6 months. This species variation in the occurrence of the metabolic peak with respect to weaning and puberty indicates that weaning and puberty are not the "causes" of the peak. Moreover, on plotting metabolism per unit area and weight gain per unit area against age a parallelism is observed between the two⁴⁷, indicating that the rise and decline in metabolism per unit area tends to be associated with the rise and decline in growth rate per unit area.

It is, therefore, concluded that the position of the metabolic peak is not due to one "cause" but is the resultant of many factors—to puberty, to weaning, to changes in growth rate, but particularly to stabilization of the neuroendocrine-homeothermic system.

An interesting feature of early postnatal metabolism of rats is that the brain metabolism per unit *weight* appears to parallel the total body metabolism per unit *surface area* (see Sect. 17.4, relating brain weight to metabolic rate in different species).

The endogenous nitrogen expense during growth appears to parallel that of basal energy metabolism.

A very brief discussion, but with many tables, is presented (Sect. 14.10) on the relation of metabolism to age and to weight generalized by the equation $Q/m = a + be^{-kt}$ and $Q/m = a + be^{-km}$ in which Q/m represents heat pro-

⁴⁴ Brody, S., and Kibler, H. H., "Resting energy metabolism and pulmonary ventilation in growing swine", *Id., Res. Bull.* 380, 1944.

⁴⁵ See especially, MacLeod, Grace, "Studies of the normal basal energy requirements", Dissertation, Columbia University, 1924, and Du Bois, E. F., "Basal Metabolism in Health and Disease", Lea and Febiger (several editions).

⁴⁷ Kibler, H. H., and Brody, S., *J. Nut.*, **28**, 27 (1944).

duction per unit weight, and t represents age. The applicability of this equation form to metabolism data is significant because it also represents growth relationships of other categories (Chs. 5, 16, 18, 19), particularly growth of neuroendocrine organs in relation to total body weight and age⁴³.

Fig. 13.9 (Ch. 13) might be included in this chapter; it shows the metabolism curves of the *same growing* animals alongside the curve relating metabolism to weight of *mature* animals of different species; so could Figs. 18.7 and 18.8 (Ch. 18) which present metabolic life curves.

Discussion and data are presented on prenatal heat production and on the heat increment of gestation, and on their relation to the weight of the newborn. The prediction values discussed are given in the following appendix.

¹ Surface area was computed from the equation, surface area in sq. meters = 0.15 (weight in kg.)^{0.75}. See Mo. Res. Bul. 89, p. 10. The heat production was computed on the assumption that one liter of oxygen has a heat equivalent of 4.825 Cal. This value is probably slightly high for the younger calves taking milk and low for the older heifers. The error incurred by this assumption is well within the experimental error.

² Computed on the assumption that 1 lb. TDN (total digestible nutrients) is equivalent to 1814 Cal or 1 gm. of TDN to 4 Cal.

³ Interpolated from page 8 of Mo. Exp. Sta. Bul. 338 covering feed records for large groups (35 to 87 animals). This represents not resting energy metabolism computed from O₂ consumption but actual total TDN consumed.

Table 14.3. Prediction Table for Resting Energy Maintenance Cost and Ventilation Rate in Growing Jersey Cattle.

¹ The heat production was computed on the assumption that one liter of oxygen has a heat equivalent of 4.825 Cal.

² Surface area was computed from the equation: surface area in sq. meters = 0.1 (weight in kg.)^{0.63}. See Missouri Agr. Exp. Sta. Res. Bull. 115, p. 30.

³ Computed on the assumption that one lb. TDN (total digestible nutrients) is equivalent to 1814 Cal. or 1 gm. of TDN to 4 Cal.

⁴ Computations for these body weights are extrapolations beyond the range of actual data.

Table 14.4a. Energy Metabolism and Pulmonary Ventilation in Growing Swine.
Prediction Table for Ventilation Rate of Growing Swine for Both Sexes.¹

Chapter 15

Maintenance Needs in Relation to Basal Metabolism, Body Size, and Productive Efficiency

It has been estimated that the . . . maintenance requirement is between 11 and 15 per cent above the starvation minimum. *Graham Lusk*

The energy cost of maintenance is the *net* dietary energy (Ch. 2) required to keep the organism in a "steady" energetic state—the net dietary energy required to replace the energy expended while carrying on "maintenance" life processes. Maintenance life is conventionally differentiated from productive life in that maintenance living does not involve the production of milk, eggs, wool, flesh, etc., or muscular work aside from that associated with carrying out the normal non-productive life processes.

The major maintenance-energy expense is the basal energy metabolism. According to the quotation at the head of this chapter, the basal metabolism is approximately 85 per cent of the maintenance energy metabolism.

The second largest expense for maintenance is the muscular expense, for example, the walking about associated with living. Now the expense of walking and similar muscular exertion is proportional to body weight, $W^{1.0}$ (Ch. 24), not to $W^{0.7}$, as is the case for basal or resting metabolism (Chs. 13, 14). However, reasoning on the basis of dimensional analysis (Chs. 10 and 17) leads to the conclusion that the larger the animal the slower and the fewer the movements, so that the voluntary energy expenditure for muscular exercise tends to parallel the basal metabolism, *i.e.*, it tends to vary with $W^{0.7}$ rather than with $W^{1.0}$.

By similar dimensional-analytic reasoning one may generalize that what is true of voluntary muscular work is true of all productive processes: other conditions being equal, the maximal, or limiting, productive capacity tends to vary with basal energy metabolism—with approximately $W^{0.7}$ —rather than with $W^{1.0}$. Kleiber¹ observed that the maximal relative food capacity, that is, the maximal value of the ratio
$$\frac{\text{maximal food energy consumption}}{\text{basal energy metabolism}}$$
 is approximately 5 in such diversely sized animals as cattle, rabbits, and chickens; from this he concluded that, other conditions being equal, productive efficiency is independent of body size².

¹ Kleiber, M., *Die Tierwelt*, **36**, 437 (1926); *Tierernahrung*, **5**, 1 (1933).

² For a review of Kleiber's work, see Brody, S., *Ann. Rev. Biochem.*, **4**, 383 (1935).

Here is how Crasemann³ exemplifies the idea by carrying out the computation on milk production of one 800-kg and of two 400-kg dairy cows.

	Total weight (kg)	Fasting metabolism (Cal/day)	Maintenance metabolizable energy cost, 1.67 times fasting (Cal/day)	Maximal metabolizable energy ingestion, 5 times basal (Cal/day)	Metabolizable energy above maintenance (Cal/day)	Milk production (Cal/day)	Conversion of metabolizable energy into milk energy (%)	Conversion of metabolizable energy above maintenance into milk energy (%)
One 800-kg cow	800	7800	13000	39000	26000	19500	50	75
Two 400-kg cows	800	9800	16400	49000	32000	24500	50	75

The efficiency of milk production is here independent of body size, and the same is probably true of other productive processes (Chs. 3 and 22), including maintenance, which is in a special category (static) of a productive process.

The foregoing discussion represents the writer's ideas which, however, are not generally accepted, as indicated by the following discussion.

In reply to the question concerning the relation of maintenance to basal energy needs, F. G. Benedict replied as follows:

"Basal metabolism is one thing. Energy-food requirements for maintenance is quite a different thing . . . I find myself quite unwilling to make any definite statement."

E. B. Forbes ended his reply to the same question by saying that "when a fish bites on a bare hook, he is indeed a poor fish", and so decided to "stick rather close to experimental evidence", and there is no experimental evidence for generalizing at this time.

H. H. Mitchell replied that the voluntary "activity increment", one of the major factors in the energy expense of maintenance, probably does not vary with the same function of body weight as does basal metabolism. However, he felt "no particular hesitation in saying that the maintenance requirement of protein, expressed in terms of body expenditures of nitrogen, will vary for adult animals with a power function of body weight", probably to the same degree as basal energy does.

The activity increment with respect to basal metabolism was reported to be 50 to 75 per cent in humans under sedentary occupation⁴; 50 per cent in poultry⁵; about 20 per cent in swine⁶; very slight in rats⁷ and cattle. Armsby⁸ computed the net energy of beef cattle maintained at constant weight in the feed lot to be approximately the same as the estimated heat production of fasting cattle in the respiration chamber. These species differences do not seem reasonable to the present reviewer and are probably due to differences in experimental methods.

In reply to this question J. R. Murlin described an elaborate experiment, as yet unpublished, which (said Murlin) "makes me believe emphatically in the idea that energy

⁸ Armsby, H. P., "Nutrition of farm animals", New York, p. 291, 1917.

requirement for maintenance under ordinary living conditions is definitely related to body surface, or, if you prefer to put it that way, to some fractional power of the body weight."

Livestock feeders usually allow so much maintenance per 100 or per 1000 lbs live weight. Thus for maintenance of dairy cattle Haecker⁹, Morrison¹⁰ (old standard), Savage¹¹, and Gaines¹² allow 8.0 lbs *TDN* per 1000 lbs live weight. Eckles¹³ 7.5; Kellner¹⁴ 6.7; Armsby¹⁴ 6.5; Forbes and Kriss¹⁴ 6.0; Möllgaard¹⁴ 5.9; Hannsson¹⁴ 5.7 lbs *TDN* per 1000 lbs live weight. No allowance was made in the ratio of *TDN* per 1000 lbs live weight for small and large cows, under the tacit assumption that, unlike basal metabolism, the maintenance energy cost varies directly with simple body weight, not with $W^{0.7}$.

On the other hand while, *e.g.*, 120-lb sheep or goats are generally thought by practical livestock feeders to need 2 lbs *TDN*/day for maintenance, 1200-lb cattle are usually thought to need not 20 but only 10 lbs *TDN*/day for maintenance, which turns out to vary in proportion not to $W^{1.0}$ but approximately to $W^{0.7}$ ($TDN = 0.0704W^{0.699}$). In the 1936 edition of Morrison's "Feeds and Feeding", the maintenance standard for horses is given to vary with the 0.73 power of body weight; and for cattle with the 0.87 power of body weight¹⁵.

It appears from Chs. 13 and 14 and from the above discussion that while we have some reliable data and agreement on the relation of basal metabolism to body weight, we have no correspondingly reliable data and agreement on the relation of maintenance energy to body weight. The reason for this deficiency in reliable maintenance data for animals of different size is, of course, the relatively great expense involved in maintaining such farm animals as cattle in statistically significant numbers in non-productive condition for statistically significant periods of time. There is particular need for maintenance data for mature animals of the same species, but differing widely in body weight. Dogs might furnish the desired range in body size, although it may be objected that dogs differing widely in body size may differ widely in their endocrines (Ch. 7) and consequently in their metabolism and maintenance needs for reasons other than body size as such.

It is obviously important to have precise data on maintenance in relation

¹⁵ Morrison, F. G., "Feeds and Feeding", pp. 77, 78, 81, and 1006, 1936. The 0.87 value of the exponent of W for cattle is the average of 1.0 of the old Henry-Morrison Standard and 0.74 which is the average of Kleiber's (0.75) and the writer's (0.73) value of the exponent $(1 + 0.74)/2 = 0.87$. We shall show later (Ch. 24) that in mature horses of different size, Percheron and Shetland, the resting metabolism varies more nearly with $W^{1.0}$ than with $W^{0.7}$.

to body size for the scientific planning of national and institutional food needs for man, for formulating maintenance feeding standards for farm animals of various live weights, and for furnishing a basis for judging whether large and small farm animals differ in efficiency as converters of feed energy into the energy of desired products. .

The introductory discussion (also Chs. 3, 21, and 23) and Crasemann's table previously cited indicate that the energetic efficiency of a productive process, such as milk production, is independent of body weight, *provided* that both the maintenance energy cost and the energy equivalent of the product vary in the same manner with increasing body weight, for example with $W^{0.7}$; but there is no agreement on this. The writer and, as previously noted, Kleiber and Crasemann believe that, when other conditions are equal, maintenance and production run parallel, and that both vary with $W^{0.7}$ (the writer) or $W^{3/4}$ (Kleiber).

Gaines¹⁶, on the other hand, believes that both milk production and maintenance cost are directly (linearly) proportional to simple body weight at the beginning of the lactation period. This, however, contradicts the fact that while superior 120-lb goats produce 10–15 lbs milk a day, 1200-lb superior cows produce not 100–150 lbs but only 50–60 lbs a day (Chs. 3, 21, and 22). Likewise, while the maintenance need of a 120-lb goat is of the order of 2 lbs *TDN* a day, the maintenance need of a 1200-lb cow is not 20 lbs but of the order of 10 lbs *TDN* a day.

So much for the energy cost of maintenance, which the writer believes varies approximately with $W^{0.7}$ rather than with simple body weight, $W^{1.0}$. The same is undoubtedly true of protein, since the ratio of endogenous or minimal nitrogen excretion to basal or minimal energy metabolism is approximately constant in animals ranging in weight from mice to cattle (Ch. 13), about 2 mg N/Cal.

As regards the maintenance needs for vitamins and trace elements, those that are involved in the general oxidation-reduction processes (Ch. 6) of intermediary metabolism, such as thiamine or riboflavin, undoubtedly vary directly with the energy metabolism, that is with the food-energy consumption, and if the energy metabolism varies with $W^{0.7}$, so must vitamin metabolism¹⁷.

To illustrate by thiamine (vitamin B₁), the minimum vitamin required is estimated to be, on the basis of various types of data in the literature, in micrograms thiamine per 100 grams dry food, 80–100 for rats¹⁸, 60 for chicks

¹⁶ Gaines, W. L., *J. Dairy Sci.*, **20**, 583 (1939).

¹⁷ Cowgill, G. R., "The vitamin B requirement of man", Yale Press, 1934. This was for "vitamin B" as a whole, requirement which author claimed to vary with $W^{0.66}$ in mature animals of different species, but (according to the reviewer's computation from Cowgill's data) with $W^{2.2}$ for growing mice, $W^{1.78}$ for growing rats, $W^{1.74}$ for growing pigeons, $W^{1.69}$ for growing dogs.

¹⁸ Arnold, A., and Elvehjem, C. A., *J. Nut.*, **15**, 429 (1938).

and turkeys¹⁹, 75 for dogs²⁰, 50 to 90 for swine²¹, 90 to 110 for man²². Exercise²³ and temperature²⁴, which increase energy metabolism, increase the thiamine need proportionately. Hyperthyroidism, which increases energy metabolism, also increases thiamine need²⁵. In general, the minimal thiamine requirement (for man) is 0.3 to 0.5 mg per 1000 Cal metabolism, and the optimal is 0.5 to 1.0 mg per 1000 Cal metabolism²⁶. The thiamine is thus proportional to the food-energy intake rather than body weight.

It is similarly reasonable to assume that riboflavin (the prosthetic group of the yellow enzyme) is required in proportion to the oxidation rate, to energy metabolism, and therefore to the food or feed intake rather than to body weight. This assumption is justified by the following estimates of minimal requirement of riboflavin in micrograms per gram dry food: rats²⁷ and poultry²⁸, 100 to 200; dogs²⁹, 200 to 400; swine³⁰, 50 to 150.

If the above and other data are represented in terms of micrograms per unit body weight, the uniformity disappears and, like metabolism per unit weight, the larger the animal the smaller this ratio of vitamin B₂ to body weight.

Animal	Riboflavin need (mcg/100 gm body wt)
Rat	100-200
Chick	150-300
Hen	50-150
Dog	10-20
Swine	2-6
Man ³¹	4-6

The data are too few to justify discussing the relation of the other members of the vitamin B complex to body weight. One would guess, however, that the pyridoxine and nicotinic acid requirements would vary with the energy metabolism rather than with simple body weight. The situation is complicated by the fact that many B vitamins are synthesized in the digestive tract.

Curiously enough, ascorbic acid (vitamin C) metabolism is said to vary with body weight³² rather than with energy metabolism. Still, guinea pigs are said to require 6 to 7 mg ascorbic acid per kg body weight, or perhaps 5 mg per kilo³³, whereas adult man and older children are said to require only 0.7 to 1.6 mg per kg body weight per day³⁴; increasing metabolism by thyroxine increases the ascorbic acid requirements accordingly³⁵.

As regards the minimal requirement of the fat-soluble vitamins, it is definitely established³⁶ that the requirement for vitamin A varies directly with simple weight, $W^{1.0}$, and not with metabolism, $W^{0.7}$. The minimal vitamin A (not carotene) is 2 to 4 micrograms per pound live weight per day in such diverse species as rats, dogs, swine, sheep, cattle, and horses³⁶. The situation is more complicated when feeding carotene (rather than vitamin A) because of species and perhaps individual differences in ability to utilize carotene. Thus rats, sheep, cattle, horses, and perhaps swine utilize carotene quite well, requiring about 10 micrograms carotene per pound body weight per day³⁶; chickens³⁷ require about 50 micrograms carotene per pound per day, although the vitamin A requirements are virtually the same for both groups.

We conclude this chapter with a "maintenance standard" for energy and protein need of animals ranging in size from 0.1 to 1000 kg and with related items.

This "maintenance standard", presented in Table 15.1 and Figs. 15.1 and 15.2, is based on *digestible* energy (TDN = total digestible nutrients, assuming that 1 lb TDN is equivalent to 1814 digestible Calories; one gram TDN is equivalent to 4 Cal; 1 gram protein and carbohydrate have heat equivalents of 4 Cal and 1 gram fat, 9 Cal) and *digestible* crude protein (DCP = "digestible" $N \times 6.25$). By employing the *digestible* nutrient category, complications associated with fecal losses are apparently not actually avoided.

This "standard" is based on the assumption that both the energy and nitrogen metabolism vary with $W^{0.73}$ rather than with $W^{1.0}$; and that the maintenance need for digestible energy, TDN , is double the basal-energy metabolism and that the digestible crude protein, DCP , is four times the protein equivalent of the endogenous urinary excretion.

In Figs. 15.1 and 15.2 the heavy curves designated by (A) represent basal metabolism, or endogenous urinary nitrogen. The lighter curves designated by (2A), (3A), and (4A) represent 2, 3, and 4 times the basal levels. The broken curves represent Henry and Morrison's feeding standards (1923) for

maintenance, which increases *directly* with body weight (curves A, 2A, etc. increase with the 0.73 power of body weight).

These "standards" are in agreement with the usual 3000 Cal and 70 to 80 grams protein maintenance allowance for a 70-kg man, and with Henry and Morrison's 1923 maintenance standard for about 500-pound farm animals.

Fig. 15.1. Line (A) designates the DCP (digestible crude protein) equivalent of urinary endogenous nitrogen excretion (1 unit DCP is equivalent to 6.25 units urinary endogenous nitrogen). Lines 2x(A), 3x(A), etc. designate respectively 2, 3 ... times the urinary endogenous level curve. Line 4x(A), representing 4 times the endogenous DCP equivalent, is the proposed DCP standard for maintenance. The broken curve represents the 1923 Henry and Morrison maintenance standard.

Our "standard" is probably equally applicable to all species of warm-blooded animals, from mice to elephants: maintenance per unit weight declines with increasing weight not only as regards energy (or *TDN*) but also as regards nitrogen (or *DCP*). As previously noted, the need for general-oxidation reduction biocatalysts (as thiamine and riboflavin, etc.) perhaps vary in similar, $W^{0.7}$, fashion.

While the "standard" in Table 15.1 and Figs. 15.1 and 15.2 is based on the assumption that the maintenance need for *TDN* calories is twice the basal-metabolism calories given in Table 13.7, we have computed (Ch. 21) the maintenance *TDN* of lactating cows by a different method—by algebraic (least squares) partitioning of the *TDN* consumed between its uses for: (1) milk production, (2) maintenance, and (3) weight gain or loss. Such algebraic partitioning of the *TDN* consumed by 243 good lactating cows gave 8.2 lbs *TDN* for maintaining a 1000-lb lactating cow. It is interesting to compare

Fig. 15.2 Line (A) designates the curve of basal metabolism; lines 2x(A), 3x(A) and 4x(A) designate respectively 2, 3 and 4 times basal energy levels. The proposed *TDN* standard represents curve 2A. (1 gm *TDN* is taken to be equivalent to 4 Cal, 1 lb to 1812 Cal). The broken curve represents the 1923 Henry and Morrison standard for *TDN*.

this maintenance value with those arrived at by other investigators employing other methods.

Fig. 15.3 shows Gaines¹⁶ graphic comparison of the various maintenance feeding standards with our suggested maintenance standard for lactating cows. The results are expressed in terms of pound *TDN* per 1000-lb live weight of cow. Frederiksen's curve is based on the assumption that *TDN* need for maintenance is proportional to $W^{2/3}$; the author's, that it is proportional to $W^{0.73}$; Morrison's (1936 ed.) that it is proportional to $W^{0.87}$. The

* Computed from equation $Y = AM^{0.75}$ in which Y represents TDN (total digestible nutrients per day = digestible crude protein + digestible carbohydrates + digestible fat $\times 2.25$), or DCP (digestible crude protein per day = $N \times 6.25$) for body weight M , and from the assumptions that TDN energy (4 Cal. per gram or 1812 Cal. per pound) is twice basal-metabolism energy, and DCP is four times the DCP equivalent of endogenous urinary nitrogen. (The nutritive ratios are thus always 1:8.7 or what is the same, 10.34% of the total calories, or of the TDN , is in the form of protein.)

other curves are based on the assumption that maintenance varies with $W^{1.0}$ i.e., with simple body weight. Fig. 15.4 compares our proposed standard

Fig. 15.3. "Digestible nutrients required for working maintenance of dairy cows of various live weight, according to 8 different feeding standards". Curves and legend from W. L. Gaines, *J. Dairy Sci.*, 20, 591 (1937).

for cows of different weight with Morrison's 1923 standard, which is, of course, the standard of Haecker and was also adopted by Savage, Gaines, and others.

As previously noted, Haecker, on the basis of one of the best and best

known investigations in this field, proposed a maintenance feeding standard of 7.925 lbs—8.0 lbs in round numbers—*TDN per 1000 lbs live weight* of dairy cow, regardless of the weight of the cow and this value was adopted by Savage, Morrison (1923 ed.) and Gaines. This value, 8.0, arrived at by observing maintenance needs of *non-lactating* cows, is somewhat below our value, 8.2, arrived at by the algebraic-partition method for 243 *lactating* cows de-

Fig. 15.4. Comparison of the 1923 Morrison feeding standard (also of Haecker, and of Savage) with our proposed (Missouri) standard.

scribed in Chapter 21, and is considerably higher than our estimated value of 6.75 in Table 15.1, based on the assumption that the maintenance *TDN* Calories is twice the basal-metabolism of *non-lactating* mature animals of different species. It is, of course, reasonable that lactating animals should have a higher maintenance cost than non-lactating. Our 6.75 value (Table 15.1) for a 1000-lb non-lactating animal is almost identical with Kellner's standard of 6.7 lbs *TDN* for a 1000-lb cow. (The other maintenance stand-

ards, for a 1000-lb cow are, as previously noted, 8.0 (Haecker, Savage, Gaines, Morrison), 7.5 (Eckles), 6.7 (Kellner), 6.5 (Armsby), 6.0 (Forbes and Kriss), 5.9 (Möllgaard), 5.7 (Hansson).

It may be observed that our algebraic-partition method (Ch. 21) also gave a *TDN* need per pound of *FCM* (milk containing 4 per cent fat) produced which agrees well with other standards. Our partition method allows 0.305 lb *TDN* per pound *FCM*; Gaines' standard allows 0.3 lb, which was abbreviated from Haecker's 0.327; Armsby, 0.285; Forbes and Kriss, 0.30; Morrison, 0.307 to 0.324; Möllgaard, 0.302; Hansson, 0.302.

It is instructive to note in conclusion that records were kept of feed consumption of mature chickens of different live weight during 28-day intervals when they were not laying eggs.³⁸ The results, shown in Fig. 15.5, indicate, to our surprise, that the feed consumption increased not with $W^{1.0}$ as poultrymen generally believe, nor with $W^{0.73}$ as we expected, nor with $W^{2/3}$ as others might expect, but with $W^{0.5}$. These unexpected results will have to be confirmed before acceptance.

Fig. 15.5. The feed consumption of domestic fowls during non-laying 28-day periods increased with, roughly, the 0.5 power of body weight, *i.e.*, increasing body weight by 100 per cent increased feed consumption by about 50 per cent.

The partition-equation method employed for evaluation of feed distribution between maintenance and egg production (Ch. 23) based on the assumption that feed cost of maintenance varies with the 0.73 power of body weight, yields, for maintenance, the equation

$$Y = 0.30W^{0.73}$$

in which *Y* is grams of the chicken feed expended for maintaining body weight in grams, *W*. Table 15.2 gives the computed values for maintenance of chickens of different live weight.

Titus³⁹ reported that "the gross maintenance requirement of White Leghorn hens, 16 months old and weighing, on an average, 1632 grams, was estimated as being 64 grams (of the special feed mixture) per bird per day during July". The corresponding maintenance feed requirement for a 1632-gram bird, as indicated in our Table 15.2 is 66.3

³⁸ Brody, S., Funk, E. M., and Kempster, H. L., Mo. Res. Bull. 278, 1938.

³⁹ Titus, H. W. *Poultry Science*, 8, 80 (1928-29).

grams, and from the table in Fig. 15.5, 67.2 grams. The three values agree satisfactorily among themselves.

By way of somewhat indirect substantiation on the way total metabolism varies with body weight, data from the literature on egg weight and body weight are brought together in Fig. 15.6. The data ranged from 0.6 gram humming-bird eggs to 1700-gram (nearly 4-lb) ostrich eggs.

Fig. 15.6. The relation between egg and body weights of different bird species ranging in body weight from 113.4 kg (250-pound) ostrich to a 2.8-gm (0.10-oz) humming bird, and ranging in egg weight from 1.7 kg (3.75-lb) ostrich to 0.6-gm (0.02-oz) humming-bird egg. The X^* (Kiwi) are not included in the equation, fitted to the data by the method of least squares. With the exception of the data for the quail, turkey, goose, and duck, which are original (Mo. Res. Bul. 278), the data were plotted from Bergtold's compilation (see text). The numerical data (first value gm body weight, second, gm egg weight) are: Ostrich (113,380-1700); Emperor Penguin (40,817-454); Toulouse goose (9072-200.8); California vulture (9070-309); Turkey (8172-85); Chinese goose (4536-165.4); Pekin duck (3629-94.5); one domestic fowl included in general equation (2041-72); Runner duck (1814-75.6); Kiwi *not included in equation* (1814-41 and 1701-397); guinea hen (1587-40); Adelle penguin (1205-130); Ring-neck pheasant (1020-34); Golden pheasant (624-28); yellow-billed tropic bird (397-40); long-eared owl (320-23); domestic pigeon (283-14); quail (185-9.4); Magpie (151-9.6); Screech owl (142-16); mourning dove (128-11); Meadow lark (113-5.7); Western robin (95-6.0); Kildeer (88-11); Western nighthawk (78-9.9); Brewer's blackbird (74-5.1); Kingbird (45-4.1); Catbird (40-1.7); English sparrow (30-2.6); House finch (19-2.3); Broad-tailed humming bird (2.8-0.6).

Fig. 15.6, based on Bergtold's compilation,⁴⁰ and on data on the domestic fowl, quail, turkey, duck and goose furnished by E. M. Funk of this Station, shows that as between different species, egg weights increase with the 0.73 power of body weight, at practically the same rate as basal metabolism of mature animals of different species. This is an exceedingly interesting result. The wide scatter of the data should not be disturbing,

⁴⁰ Bergtold, H., "A study of incubation period of birds. What determines their length?" The Kendrick-Bellamy Co., Denver, Colorado, 1917.

considering the fact that in many cases the body weights were taken from one observer, and the eggs from another, and that a change in body weight, due to increase or decrease in body fat, does not appreciably affect the *egg* size. This increase in egg weight with $W^{0.73}$ rather than with $W^{1.0}$, indicates to the writer that the total metabolism parallels the basal metabolism, and what is true of egg production is likely to be true of other productive processes. A similar result was found (Ch. 22) for milk production in rats, goats, cattle, and man.

Summarizing this chapter, while we have reliable data on basal energy and endogenous nitrogen (Chs. 13 and 14), we do not have data of comparable reliability on the maintenance cost. It appears, however, that the maintenance needs for energy, protein, and dietary catalysts (*e.g.*, thiamine and riboflavin) which participate in the general oxidation processes vary in the same manner as the basal energy and endogenous nitrogen metabolism, namely with approximately $W^{0.7}$.

To be sure some types of metabolism vary directly with simple body weight. This is true of creatinine, which is a part of the endogenous-nitrogen metabolism varying with $W^{0.7}$, yet itself varies with $W^{1.0}$, in both mature animals of different species and in the same animals when growing. About 15 mg creatinine are excreted per kilo body weight⁴¹ in rats of all weights, and also in cattle and man. Likewise, as regards vitamin A, which is needed in proportion to $W^{1.0}$ rather than to $W^{0.7}$. The mineral need may be in proportion to body weight. But in general, those processes involving oxidation vary with $W^{0.7}$ rather than with $W^{1.0}$. The energy expense of muscular exercise varies in proportion to $W^{1.0}$ rather than to $W^{0.7}$ but, in most animals, increase in size is associated with decrease in the frequency and rapidity of movements, so that perhaps the energy expenditure for spontaneous exercise associated with a maintenance life varies with $W^{0.7}$ rather than with $W^{1.0}$. This reasoning, that total metabolism varies with basal metabolism or with $W^{0.7}$, is in harmony with dimensional analysis (Chs. 10 and 17) and with such observations as that milk production (Ch. 22) and egg production (Fig. 15.6) varies with $W^{0.7}$ rather than with $W^{1.0}$, and that the ratio of maximal food-energy intake to basal metabolism is independent of the size of the animal. There are exceptions in detail, but this appears to be the general rule.

Chapter 16

Time Relations of Growth of Individuals and Populations

All motion of natural action is performed in time. *F. Bacon*

Everything exists not only in a frame of space but also in a pattern of time.

G. E. Coghill

As early as the fifth century B.C., Greek physicians developed a very clever method for the study of growth which is employed by scientists down to our day. A hen was set upon a number of eggs; each day one of these eggs was opened and the changes that took place could be observed. *H. E. Sigerist*

16.1: Introduction and definitions. The use of isotopes in the study of metabolic processes has shown that, perhaps, all constituents of the living cell are involved in continuous chemical reactions, continuous breaking down and building up—catabolism and anabolism. It is only the pattern, the life whirlpool, that endures. Biologic synthesis, that is, the interaction of exogenous material (food) in the formation of new chemical-morphological units, thus occurs not only during the period conventionally designated as growth, but throughout the entire life cycle¹.

The occurrence of widespread synthesis throughout life may also be observed without refined metabolic studies. Thus blood cells and epidermis have long been known to undergo rapid destruction and renewal; there is a continuous need for growth catalysts (hormones, vitamins, etc.) and structural materials (amino acids, minerals) to compensate for the continuous losses, breaking down, or catabolism, of the body. These constructive processes are more dramatic during periods following starvation and injury, especially regeneration of limbs in lower forms of life.

The most spectacular type of directed biosynthesis is, of course, growth and development, especially during embryonic life. Everyone has been impressed by the miraculous transformation of the sticky white and yellow mass of hen's egg into a fully dressed, befeathered, respectable chick, all in 21 days. The original egg cell must have travelled at a dizzy pace to build up so complex a mechanism—probably exceeding in complexity the astronomical wonders with their galaxies and supergalaxies.

¹ Schoenheimer, Rudolph, *Physiol. Rev.*, **20**, 218 (1940); *Growth*, Second Supplement, p. 27 (1940); "Dynamic state of body constituents," Harvard University Press, 1942 (ed. by H. T. Clarke).

Growth as thus defined is inseparable from metabolism, and the several chapters in this book are merely different aspects of essentially the same problem, metabolism-growth. Thus Chapter 6 is concerned with enzymes in metabolism, in biologic synthesis; Chapter 7, with hormones; Chapters 13 to 15, with "maintenance" catabolism;

Fig. 16.1. Photographs ($\times 135$) of rabbit eggs during 4 days after fertilization. A, 1-cell stage with 2 polar bodies; B, two primary blastomeres, about 25 hours after; C, 4-cell stage 29 hours after copulation; D and E, 6-cell and 8-cell stages 32 hours; F, 32-cell morula 55 hours; G, morula 70 hours; H, trophoblast cells, 71 hours; I, fluid collections in the forthcoming segmentation cavity 77 hours; J, segmentation cavity 90 hours; K, inner-cell mass flattening into germ-disk 92 hours. From P. W. Gregory [Plate I, *Carnegie Inst. Wash.*, **21**, 407 (1930)], arranged by G. L. Streeter [*Sci. Monthly*, **32**, 498 (1931)].

Chapter 20, with general nutritional aspects, and so on. This chapter is concerned with the definitions and time relations of average development and growth in weight of the body as a whole.

Development refers to the *directive* coordination of the diverse processes into an adult—into an “organized heterogeneity” (Needham). Some types of growth are not developmental: Teratomata are jumbles of hair, teeth, nerve, etc. Cancerous growth, like growth of tissue cultures *in vitro*², is without *directive* significance outside of self-multiplication.

Growth is biologic synthesis, production of new biochemical units. It is the aspect of development concerned with increase in living substance or protoplasm, and includes one or all of three processes: (1) cell multiplication, (2) cell enlargement, (3) incorpora-

Fig. 16.2. Increase in cell number of tubal ova in several species, modified from Fig. 29, p. 89, “The Eggs of Mammals,” Gregory Pincus, Macmillan Co., “Experimental Biology Series,” New York, 1936, from data by Gregory (rabbit), Carnegie Inst. Wash., *Contrib. Embryol.*, **21**, 141 (1930), and Pincus, G., *Proc. Roy. Soc.*, **107**, 132 (1930); Lewis, W. H., and Wright, E. S., (mouse) Carnegie Inst. Wash., *Contrib. Embryol.*, **25**, 113 (1935); Lewis, W. H., and Hartman, C. G., (monkey) *Id.*, **24**, 187 (1933); Heuser, C. H., and Streeter, G. L., (pig) *Id.*, **20**, 1 (1929); Gilchrist, F., and Pincus, G., (rat) *Anat. Rec.*, **54**, 275 (1932).

tion of material taken from the environment. The cleavage of the egg into daughter cells is growth by cell multiplication, not by cell enlargement nor by incorporation of material from the outside. Blood corpuscles, monocytes, hair-follicle cells, and ectoderm cells always grow by cell multiplication. Nervous tissue and skeletal-muscle tissue grow by cell enlargement, not by cell division. The inclusion of non-protoplasmic substances, such as fat, blood plasma, cartilage, etc., is an increase by incorporation of

² Cf. Lewis, W. H., “Symposium on Development and Growth,” First Supplement to *Growth* (1939).

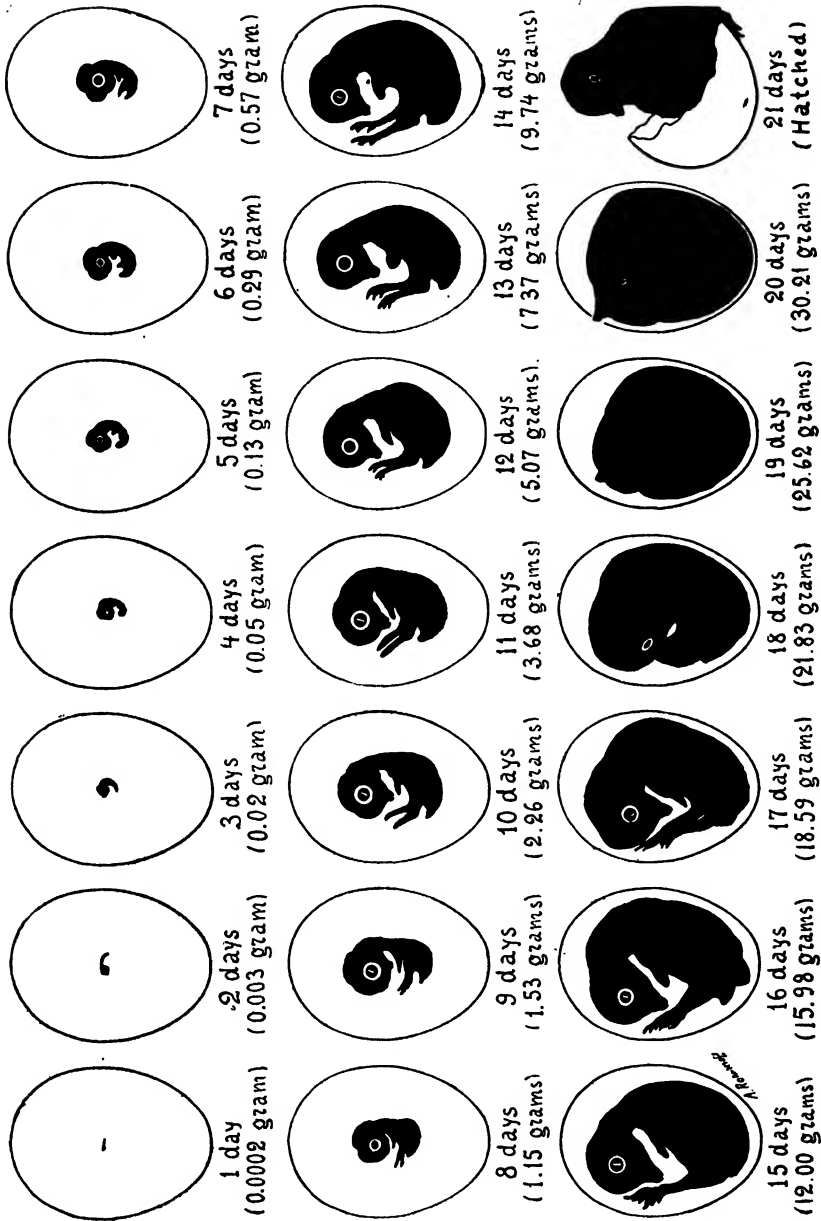

Fig. 16.3a—See legend for Fig. 16.3b

material from the environment, involving neither cell multiplication nor cell enlargement. Such increase is not regarded as "true" growth. Yet operationally, from the standpoint of quantitative measurement of growth of the organism as a whole, we must consider these non-protoplasmic inclusions—if they are irreversible—as parts of the growth process.

¹ Fig. 16.3 a, b. Domestic fowl's egg and its development, from A. L. Romanoff, Cornell Exp. Bull. 205, 1931 and 1936. Beginning of alimentary tract, 18 hours; vertebral column, 20 hours; nervous system, 21 hours; head, 22 hours; blood island-vitellin circulation, 23 hours; eye, 24 hours; ear, 25 hours; heart beat, 42 hours; amnion, 50 hours; legs and wings 63 hours; allantois, 70 hours; reproductive organs, 5th day; feathers, 8th day; beak turns toward air cells, 17th day; yolk sac begins to enter body cavity, 19th day; yolk sac completely drawn into body cavity, 20th day; hatching of chick, 21st day.

The knowledge of the mechanism whereby the protoplasmic mass increases is in its initial stages of investigation³ is not understood.

³ For literature see Gulick, A., *Growth*, 3, 241 (1939); *Advances in Enzymology*, 4 (1944). Bergman, M., *Chem. Rev.*, 22, 423 (1938). Wrinch, Dorothy, *Protoplasma*, 25, 550 (1936); *Proc. Roy. Soc.*, 161A, 505 (1937). Mark, H., *Nature*, 140, 8 (1937). See also many papers by F. S. Hammett in *Growth* indicating the functions of various amino acids and other substances in growth of the hydroid *obelia*; Schoenheimer,¹ and Supplements 2, 3, and 4 (1940-42) to *Growth*.

Differentiation (cytogenesis, histogenesis) is transformation of mother cell, such as egg cell, into *different* kinds of daughter cells—brain cells, kidney cells, liver cells, etc. This process is irreversible. Egg cells are transformed to liver cells, but liver cells cannot be transformed into egg cells. There is a running down of growth potentialities with increasing differentiation in the individual, analogous to running down of free energy in the larger universe (Ch. 2).

Morphogenesis (organogenesis), another aspect of development, refers to the organization of the various cells into special organs of definite form, and the organization of the organ-systems into the body as a whole.

Fig. 16.4. Three methods of representing growth: (1) broken curve, absolute time gain; (2) declining curve with triangles, instantaneous percentage rate of growth $\left(100 \times \frac{\ln W_2 - \ln W_1}{t_2 - t_1}\right)$; (3) rising S-shaped curve, cumulative or course of growth, or the total weight at given age.

Needham⁴ subdivides *growth* into: (1) cell multiplication, (2) intussusception, or increase in size of cells, and (3) accretion or increase in amount of non-living structural matter; *differentiation* into: (1) increase in number of kinds of cells, and (2) increase in morphological heterogeneity; *metabolism* into: (1) respiration (oxidation), (2) fermentation or glycolysis, (3) catabolism of protein, (4) catabolism of fat, (5) chemical activity, as pigment-formation, glycogen synthesis, etc.

Other authors have other schemes of classifications. We defined development to include growth; Hammett defined growth to include development—growth is the co-

⁴ Needham, J., *Biol. Rev.*, 8, 180 (1933).

ordinated expression of incremental and developmental factors and functions⁵. In this chapter, concerned not with growth mechanisms but with time relations, growth is defined operationally by increase in weight.

The bird's egg is deceptively large because of its "cleidoic" nature⁶, its yolk and albumen stores and related "redundant structures", such as air chambers for the nutrition of the embryo. In contrast, the mammalian egg is a minute speck. The mammalian egg, first observed in 1827 in the dog⁷, appears to be nearly independent of the size of the mature animal. It ranges⁸ from about 70 to 85 μ (μ is $\frac{1}{1000}$ millimeter) in rodents (mice, rats, guinea pigs) to about 140 μ in dogs, horses, sheep, goats, pigs, whales, and primates, including man. In other words, the egg of mouse, man, or whale is of practically the same size, about $\frac{1}{10}$ millimeter in diameter. Yet, a given egg grows, differentiates, and develops into chick, mouse, man, or whale and goes through life according to its respective inherited pattern.

Fig. 16.5. Comparison of growth of populations and of individuals. For data and sources see R. Pearl, "The Biology of Population Growth," A. Knopf, N. Y., 1925.

The general appearance and cleavage of the egg of cow, pig, cat, muskrat, monkey, and man are similar^{9, 10}, as exemplified by Fig. 16.1 from Gregory¹⁰ and Fig. 16.2 from various sources compiled by Pincus¹¹.

¹¹ Pincus, G., "The eggs of mammals," Macmillan Co., 1936.

Under great magnification the fertilized mammal's egg is seen to contain particles in motion, in agitation, eventuating in cleavage of the egg cell into two daughter cells. In this division, as in perhaps the following 3 or 4 cleavages, there is no increase in the mass as a whole, but only subdivisions of the cells.

This basic process of division of one cell into two, the nature of which is not understood, is one of the most distinguishing characteristics of living organisms. An even more remarkable example of division, inexplicable by known physical forces, is the production and expulsion of polar bodies by the unfertilized egg in preparation for the reception of the sperm's contribution to the *zygote*¹². This "anticipation" of future developmental needs of both the individual and the race sets living processes apart from non-living. Similarly, other structures develop in anticipation of—and long before—the time when they will be called upon to function in the service of the organism as a whole (Ch. 10).

Fig. 16.6. Equivalent growth curves of rats, yeast populations, maize plant, oat plant, and a squash.

There is no pronounced increase in the size of the mass in the first few cleavages of the fertilized egg, but there is increasingly pronounced differentiation so that at the 16-cell stage the *trophoblasts*, the cells destined to furnish the fetal membrane, and the structures of implantation of the egg on the maternal tissue, become distinctive. The trophoblast cells divide more rapidly and are, therefore, smaller than the other cells.

Next most conspicuous is the formation of the fluid-distended vesicle, the *blastocyst* (Fig. 16.1), and cupping into a hollow sphere. Fluid collects within this sphere, perhaps through the secretory activity of the trophoblast cells, and the cell mass, for the first time, enlarges by the accumulation of fluids.

The outstanding feature of the "growth" of the blastocyst is the absorption of tremendous quantities of water. Davenport¹³ estimated that after six weeks the human

¹² Zygote, the "yoked" first cell of the body, the union of male and female germ cells, or gametes, carriers of the genes or hereditary determiners.

¹³ Davenport, C. B., "How we came by our bodies," New York, 1936.

egg is nearly 500,000 times its initial weight, weighing about a gram, the increase in weight being 98 per cent water. Water is economical for growth and gives plenty of "elbow room" for the developmental processes; it is the solvent and carrier of nutrients and wastes, and there must be plenty of it prior to the development of the circulatory system.

The blastocyst forms the embryonic envelope and establishes contact for the interchange of fluids between embryo and mother. After the attachment of the egg, the inner cells begin segmentation and differentiation to form the embryo and the amniotic and yolk-sac vesicles form. The two vesicles flatten against each other and, together with the cells between them (mesoblast cells), form a three-layered germ disk which forms the embryo. The remainder is, like the trophoblast, accessory and temporary. The germ disk is formed in man about the third week.

Fig. 16.7. Weight-growth equivalence of farm animals, laboratory animals, and man.

The cupping in of the amniotic and yolk-sac vesicles to form the germ disk is mechanically somewhat analogous to the cupping in of the two walls of a hollow rubber ball, and is in a way characteristic of the successive infoldings during organ formation.

The layers interact in the production of new kinds of cells, the segregation and differentiation of which eventuate in organ formation (Fig. 16.3). In man, the external features of the embryo are easily recognizable as distinctively human by the latter part of the second month. Eyes, mouth region, and limb buds may be recognized by the fourth

week in man, and the organs are formed by the third month. In other words, the "ground plan" is laid very early in life and rounded out later through enlargement and remodeling of the parts. Age changes in shape are due to differences in growth rates of the constituent parts (Ch. 17).

There is an orderly sequence, or *gradient*¹⁴, in organ formation. The head has precedence in development over the tail end, and so on in cephalochordal sequence for the other organs. The sequences may be associated with organizer and hormone action (Ch. 7).

Fig. 16.8. Comparison of weight gain and specific mortality in children.

With these brief definitions and introduction we proceed with our major problem, an analysis of the time relations of growth in weight.

Many of our gigantic industrial organizations are extremely complex; no one can know all their details. Yet accountants, quite ignorant of these details, render intelligible and useful corporate statements. Likewise,¹⁵ the

¹⁴ Cf., Child, C. M., "Individuality in organisms," Univ. Chicago Press, 1915.

¹⁵ Cf. Bertalanffy, L. V., "Theoretische Biologie, Berlin," 1932; also *Roux Arch.*, **131**, 613 (1934), and *Human Biology*, **10**, 181 (1938).

animal body is extremely complex; no one can know all its details. Yet, as we shall show in this chapter, the time relations of growth can be represented by intelligible, useful, and rational statements or "laws" of growth.

Fig. 16.9. The relation between the percentage growth rate computed by the instantaneous logarithmic and by the finite arithmetic method.

It may be recalled in this connection, that some of the great laws of the physical sciences, such as Newton's law of gravitation, say nothing about detailed mechanisms involved; they are only intelligible, useful, and more or less rational descriptive statements of the phenomenon. There is, of course, a wide range in rationality in many so-called "laws" of nature. We hope that the following growth equations partake more of laws of nature and less of the accountant's purely empirical rendering of a financial statement.

Fig. 16.10. Growth of the white rat between 13 days after conception and 10 days after birth, plotted on arithlog and on arithmetic coordinate paper.

16.2: The shape of the age curve of growth of individuals and populations

There is no bound to prolific nature in plants and animals but what is made by their crowding and interfering with each other's means of subsistence. *T. R. Malthus* (1798)

Fig. 16.5 represents age curves of growth of *populations* of yeast and flies, and of *individual* pumpkins and rats. They all have the same s-like shape. Indeed, all these curves may be made to coincide, as shown in Fig. 16.6.

Fig. 16.7 demonstrates the close similarity between the age curves of different animal species. The human age curve, however, differs from the others in having a very long juvenile period, a long interval between weaning and puberty (approximately 3 to 13 years); this period is almost absent in laboratory and farm animals. In these animals, weaning merges into adolescence without the intervention of the juvenile phase found in man. The uniquely long juvenile period in man should be of particular interest to students of education.¹⁶

Fig. 16.11. The true percentage growth rate of three sets of rats during the first ten days of postnatal life.

The general similarity between the curves of growth of individuals and of populations is not surprising, since ultimately both are collections of individuals. Our bodies are made of cells, and our bodies, in turn, are cells in the social body. Individuals are organisms and also units of a larger organism, an epiorganism (Sect. 10.9).

¹⁶ Cf. Fiske, John, in "The Meaning of Infancy"; Boston, 1883: "If there is any one thing in which the human race is signally distinguished from other mammals, it is the enormous duration of their infancy . . . this period of helplessness . . . is a period of plasticity . . . a door through which the capacity for progress can enter . . . power to modify . . . inherited tendencies."

It may be seen from Fig. 16.4 that the age curve of growth may be divided into two principal segments, the first of increasing slope, which may be designated as the *self-accelerating phase of growth*, and the second of decreasing slope, which may be designated as the *self-inhibiting phase of growth*.

The general shape of the age curve may thus be said to be determined by two opposing forces: a *growth-accelerating force* and a *growth-retarding force*.

Fig. 16.12. Postnatal growth of rat to the pubertal inflection

The former manifests itself in the tendency of the reproducing units to *reproduce at a constant percentage rate indefinitely, when permitted to do so*. In the absence of inhibiting forces, the number of new individuals produced per unit time is always proportional to the number of reproducing units. That is; the *percentage growth rate tends to remain constant*. The potentially infinite growth ability and consequent immortality of somatic cells was established by Leo Loeb¹⁷ by *in vivo* experiments with cancer tissue (trans-

¹⁷ Loeb, L., *J. Med. Res.*, **6**, 28 (1901), and *J. Gen. Physiol.*, **8**, 417 (1926).

plantation of the cancer tissue to successive generations of animals), and verified by Carrel¹⁸ by *in vitro* experiments with normal connective and other tissues, by cultivating tissue cells *in vitro* under conditions of continuous irrigation, thus preventing change in environment which would result in the development of growth-inhibiting forces.

But there comes a time, marked especially by the inflection in the growth curve, when the increase in the population tends to be proportional not to the number of reproducing individuals in the population but to the available resources necessary for growth; the resources may be in the form of space,

Fig. 16.13. Illustration of the discontinuous nature of the growth process by the daily weight increments, and the fit of the equation (16.6) to the increment curves.

food, freedom from the encroaching by-product of growth, as lactic acid in the case of growth of lactic acid bacteria in milk. It is the environment—or the growth-inhibiting force in the environment—which exerts the limiting influence on growth after the inflection in the curve.

And so, with the passage of time, the growth-inhibiting force or forces develop, counteracting and finally bringing the growth process to a virtual standstill.

¹⁸ Carrel, A., *J. Exp. Med.*, **38**, 521 (1933). Carrel and Ebeling, A. H., *Id.*, **34**, 317 and 599 (1921).

The inflection in the age curve (Figs. 16.4 to 16.8 and 16.13) represents the position at which the increase in growth velocity ceases, and the decrease in velocity has not yet begun; therefore, the inflection represents the position at which gains are most rapid, and perhaps most economical (Figs. 16.4 and 16.8).

At the point of inflection the *change* in the time rate of growth (*i.e.*, in acceleration) is the same in all animals or populations (the numerical value of the acceleration at this time is zero). This is, therefore, a point of geometric and physiologic age equivalence. There is at least one physiological

Fig. 16.14. The percentage rate of growth of lactic-acid bacteria is constant until pH 4.73 is reached. The acid increases at 47 per cent per hour, or is doubled in $\frac{0.69}{0.47} = 1.5$ hours.

stage through which all animals seem to pass at this time, *i.e.*, puberty. Thus in Fig. 16.4 the inflection in the curve of the female rat occurs at about 65 days (86 days after conception), and this is the usual age at which the vagina opens. In children the inflection occurs between 12 and 15 years, the age of puberty.

A third fact relating to children, and possibly to animals also, is that the curve of specific mortality (*i.e.*, the ratio of the number dying to the number living of the same age) passes through a minimum at approximately the same age as the growth curve passes through its inflection. This is shown in Fig. 16.8. The specific mortality decreases to this age, and increases thereafter.

Fig. 16.15. Growth of *B. coli* at 37°C. in a given volume of broth [Exp. 7, McKendrick and Pai, *Proc. Roy. Soc. Edinburgh*, **31**, 649 (1911)]. As $k = 1.85$, growth was at 185 per cent an hour; the population is doubled in $\frac{0.693}{1.85} = 0.37$ hour, or 22.2 minutes.

The point of inflection, then indicates: (1) the time of maximum velocity of growth (transition from increasing to decreasing growth velocity); (2) the age of puberty; (3) the lowest specific mortality, the beginning of the period of increasing specific mortality; and (4) a geometric referent for the determination of equivalence of age in different animals (and also equivalence of age in the growth of populations). The point of inflection is thus an important growth constant. Figs. 16.7 and 16.8 show that the inflection in man occurs at the age of about 14, which corresponds on the axis of ordinates to somewhat over 60 per cent of the mature weight. In chimpanzees the inflection (at age seven years) occurs at slightly below 60 per cent of the mature

body weight.¹⁹ In laboratory and farm animals (Fig. 16.7), on the other hand, the inflection takes place when about 30 per cent of the mature weight is reached, corresponding to about six months in cattle, or two months in sheep.

Summarizing, the shape of all age curves of growth, whether of individuals or populations, is sigmoid; the early phase is of rising slope and the later

Fig. 16.16. Growth of the human population in the North American Colonies and in the United States. $k = .029$; the population increased at 2.9 per cent per year, doubled itself in $\frac{0.693}{0.029} = 24$ years. (From data in "A century of population growth in the United States" by W. S. Rossiter, Bureau of the Census, United States Department of Commerce and Labor, Washington, 1909).

phase of declining slope. The junction between the two phases occurs during puberty in animals, flowering in plants, and "coming of age" in populations, when, because of the back pressure of the environment, the reproductive rate declines or the excess population sets out on migrations, such as the dramatic migration of the lemming to the sea.

16.3: Definitions and quantitative representations of growth rates

If nature were our banker, she would not add the interest to the principal every year; rather would the interest be added to the capital continuously from moment to moment. *J. W. Mellor*

For purposes of *quantitative* analysis, growth may be defined as relatively *irreversible* time change in magnitude of the measured dimension or function.

Fig. 16.17. The percentage rates ($100k$) of growth of the albino rat plotted against age. These are, of course, computed values, computed by the graphic method explained in the text. The curve illustrates in a striking manner the discontinuous nature of the growth process.

The concept of irreversibility is emphasized to exclude fluctuating time changes of a fortuitous nature, such as those occasioned by fluctuating food supply with consequent fattening and leaning, with gestation, lactation, and so on.

Growth in weight is usually represented in one or all of the three ways shown in Fig. 16.4: (1) *absolute* gain in the given magnitude per unit time; (2) *relative* rate (or *percentage* when multiplied by 100) gain per unit time; (3) *cumulative*, or *course-of-growth* weight up to, or the weight at, a given time. All these forms of representation may be made in conventional mathematical terminology.

Thus the absolute gain in the observed-weight difference, $W_2 - W_1$, for the corresponding time difference, $t_2 - t_1$, may be represented by the equation

$$\text{Average absolute growth rate} = \frac{W_2 - W_1}{t_2 - t_1} = \frac{\text{larger weight less smaller weight}^{20}}{\text{larger time less smaller time}} \quad (1)$$

Fig. 16.18a. Carbon dioxide excretion in the chick embryo. From 0 to 4 days the rate of increase is 98 per cent per day (doubled once in 0.7 day or in 17 hours); between 4 and 14 days, the rate is 31 per cent per day (doubled in 2.2 days). The pause in the curve coincides with the maximum in the mortality curve (Fig. 16.20), and with the change in the mode of respiration (see text).

Equation (1) represents *average* absolute growth rate, in contrast to *true* growth rate applicable to extremely short intervals of time only. If a Holstein cow weighs 1000 pounds at age 1000 days from conception, she gained on the *average* one pound a day; but there was no day when she actually gained

²⁰ Cf. Hayes, F. R., and Armstrong, F. H., *Can. J. Res.*, **21**, 23 (1943).

exactly one pound. To cite extreme illustrations, at the end of the first week after conception, she gained only about 0.0001 pound a day; at 5 months after birth, 2 pounds a day; at 1000 days, only one-fourth a day. Thus the concept of *average rate*, when applied to growth, is an abstraction, and when the average extends over a considerable period of time, as in the example cited, it gives no idea of the actual rate at any given age. The shorter the interval of time for which the average is computed, the more nearly does it approach

Fig. 16.18b. Nitrogen storage in the silk worm, from data by Luciani and Lo Monaco. The nitrogen curve of the silk worm embryo is similar to the CO_2 excretion curve of the chick embryo.

the true value; and when reduced to an interval, dt , so short that there is no time for the velocity of growth to change, the true growth rate, dW/dt , is obtained. *True growth rate* is then *instantaneous growth rate*, dW/dt .

Similarly, *relative* (or when multiplied by 100, *percentage*) growth rate is conventionally represented by the weight gain during a given time interval divided by the weight of the organism, W_1 , at the *beginning* of the time interval:

$$\text{Average relative growth rate, } R = \frac{W_2 - W_1}{W_1} \quad (2)$$

Here again we have not *true* or *instantaneous* growth rate, but the conventional (Minot's) growth rate. The conventional and true percentage growth rates are nearly identical when the weight gain, $W_2 - W_1$, is very small *in comparison* to the weight of the organism. But when the weight gain is relatively

Fig. 16.19. Carbon dioxide excretion in the chick embryo, from three sources. The percentage rates were obtained by subtracting the natural logarithms of the successive values, and multiplying the result by 100. The fluctuations between 4 and 14 days are slight and there is no systematic change in the rate.

large compared with the body weight, the conventional growth rate computed from equation (2) may be misleadingly exaggerated, because the weight at the

beginning of the time interval, W_1 , existed a relatively long time ago, not at the time of observation. Thus the computed percentage growth rate of the population in this country would be enormously exaggerated if the population gain from 1666 to 1940 were related to the population size in 1666. The population gain during 1940 must be related to the population size during 1940, not during 1666. Likewise, the relative growth rate of an animal at a given age must properly be related to the body size at the given age, not the body size, W_1 , of some earlier age, t_1 .

Another objection to Minot's equation (2) for computing percentage rate is its failure to recognize that the *physiologic* significance of a physical unit of time, such as a day, changes rapidly with age. The growth rates computed by equation (2) are for continuously decreasing *physiological* time intervals, even though they are for constant astronomic or *physical* time intervals. The use of instantaneous rates eliminates the discrepancy between *physiologic* and *physical* time (Ch. 19).

Fig. 16.20. Percentage mortality in the chick embryo. Circles represent embryos in an incubator; crosses, incubation under hens. The first peak in the mortality curve corresponds to the peak in concentration of lactic acid as reported by Tomita. The second peak in the mortality curve coincides approximately with the pause in the growth curves.

A more appropriate denominator would be the *average* weight of the organism during the time of observation. Thus if the weights of the organism at the beginning and at the end of the interval are respectively W_1 and W_2 , then the average weight during the interval is $\frac{1}{2}(W_2 + W_1)$. Replacing W_1 in equation (2) by $\frac{1}{2}(W_2 + W_1)$, we obtain

$$\text{Average relative growth rate} = \frac{W_2 - W_1}{\frac{1}{2}(W_2 + W_1)} \quad (3)$$

Although equation (3) is an improvement over equation (2), it is still physiologically unsatisfactory because (1) the time intervals, $t_2 - t_1$, are arbitrary and not equivalent physiologically for successive stages of development; (2) the weight increments are assumed by this method to be added on at discontinuous time intervals; (3) the denominator, $\frac{1}{2}(W_2 + W_1)$, is obtained

on the assumption that the growth rate occurs in a linear manner, which in practice is true only for short intervals.

In place of finite weight gain, $\frac{W_2 - W_1}{t_2 - t_1}$, we use "instantaneous" weight gain, dW/dt , and divide the "instantaneous" gain by the weight at the time of the gain, thus:

$$\text{Instantaneous (true) relative growth rate} = \frac{dW/dt}{W} \quad (4)$$

In this case, the denominator, W , represents the weight of the animal *at* the instant the rate dW/dt is measured, not the weight, W_1 , at some earlier age.

Fig. 16.21. The course of CO_2 excretion in the chick embryo plotted from data by Hasselbalch and by Murray.

It is, of course, impossible to measure the *instantaneous* rate of growth in the laboratory, because of the finite time interval required for making a measurement; but even if it were possible, the experimental errors of measurement would be greater than the instantaneous gains. Here abstract mathematics is used to solve a practical problem. The infinite number of infinitesimal instantaneous rates are added up, or integrated. (The method of integrating is explained in elementary calculus text-books.) The method is outlined symbolically in the following equations.

$$\frac{dW}{dt} = kW \quad (5)$$

$$\int_A^W \frac{dW}{W} = k \int_0^t dt \quad (6)$$

$$\ln W = \ln A + kt \quad (7)$$

$$W = Ae^{kt} \quad (8)$$

In the above equations dW/dt represents instantaneous *absolute* growth rate; $\frac{dW/dt}{W}$ and k represent instantaneous *relative*, or, when multiplied by 100, *percentage* growth rate; e is the base of natural logarithms, $\ln W$ is the natural logarithm of weight W at time t , and A is the natural logarithm of W when $t = 0$.

For purposes of computing the numerical value of the instantaneous relative growth rate, k in equation (8) is written in the form

$$k = \frac{\ln W_2 - \ln W_1}{t_2 - t_1} \quad (8a)$$

That is, the instantaneous relative growth rate, k , is the difference between the *natural* logarithms of weights W_2 and W_1 , divided by the time interval

Fig. 16.22. Postnatal growth of the domestic fowl during the self-accelerating phase of growth. During the first month, the growth rate is 5 per cent per day (body doubled in 13.8 days). During the following 7 weeks, the growth rate is 3 per cent per day (body is doubled in 23 days).

$t_2 - t_1$. Thus the practically impossible task of *measuring* the instantaneous growth rate is made possible by a mathematical device.

The constant k has a perfectly definite meaning. It is the instantaneous relative rate of growth for a given unit of time. Thus, for the growth of the fetus of the albino rat, from 14 days to birth, the value of k is 0.53; this means that the instantaneous percentage rate of growth is about 53 per cent per day or $53 \times 30 = 1590$ per cent per month; or $53 \times 7 = 371$ per cent per week, etc. As regards the constant A in equation (8), theoretically it has the value of W when $t = 0$. For the rat, A was found to be 0.00065 gram. This does not imply that at conception the fertilized egg weighs 0.00065 gram, for the constant was obtained on the basis of data from 14 to 22 days only, and one is not justified in extrapolating this value to conception. While, therefore, A has a definite theoretical meaning, practically no significance should be

attached to it. Until data become available which indicate the justification of extrapolating the curve to conception, it need be considered merely as a parameter of the equation.

Fig. 16.23a. Prenatal weight growth of the chick embryo and of its constituents and metabolites plotted from several sources on arithlog paper with indicated slopes.

It is instructive to indicate the relation between the instantaneous percentage growth rates as computed by equation (8a) and the conventional percentage growth rate computed by equation (2), which is the method proposed by Minot²¹, used almost universally by biologists until the appearance of our 1927 paper²².

We may take for illustration the data on fetal growth of the albino rat²³, ages 13 to 22 days. According to Minot, the computation for evaluating relative rates of growth is carried on as follows:

Fig. 16.23b. Prenatal weight growth in man, plotted from Streeter on arithlog paper. During the period 50 to 100 days prenatal life, growth occurs at 8 per cent per day (body weight is doubled once in 8.7 days); between 160 and 230 days, at 1.7 per cent per day (body weight doubled in 41 days); between 240 and 280 days at 1.3 per cent per day (body weight doubled in 55 days). Eight per cent per day is equivalent to 240 per cent per month; 1.7 per cent per day is equivalent to 51 per cent per month; 1.25 per cent per day is equivalent to 37.5 per cent per month.

Take the weight at a given age, and the weight at the next older age for which there are observations. From these data calculate the average daily increase in weight for the period between the two determinations of weight, then express the daily increase in percentage of the weight at the beginning of the period.

²¹ Minot, C. S., "The problem of age growth and death," New York, 1908; also *J. Physiol.*, **12**, 97 (1891).

²² Univ. Mo. Agr. Exp. Sta. Res. Bull. 97, 1927. See also Schmalhausen, I., *Arch. Entw. Entwicklunsmech. Organ.*, **109**, 455 (1927); **110**, 33 (1927); **124**, 82 (1931).

²³ Stotsenburg, J. M., *Anat. Rec.*, **9**, 667 (1915).

We have shown²⁴ that our *instantaneous* growth rate, k in equation (8), is related to Minot's *finite* growth rate, R in equation (2), by the logarithmic function

$$k = \ln(R + 1)$$

as illustrated by Fig. 16.9. The difference is particularly striking in growth rate beyond about 10 per cent, as illustrated by the following numerical examples.

At age 13 days, $W_1 = .040$ gram and at 22 days $W_2 = 4.630$ grams. The percentage growth rate, according to the method of Minot (eq. 2), is then $\frac{4.630 - .040}{.040 \times 9} \times 100 = 1275$ per cent per day; according to our method, the true or instantaneous percentage rate,

k (eq. 8a), is only $\frac{\ln 4.630 - \ln .040}{9} \times 100 = 52$ per cent per day; depending on the method used, the same set of data yields 1275 per cent or 52 per cent growth rate.

Fig. 16.24. Juvenile growth in man. Well-nourished children grow at an approximately constant percentage rate between 5 and 15 years (about 10 per cent per year; the body weight is doubled once in about 7 years). The prepubertal acceleration, so conspicuous in the literature on growth of children, is usually found only in the curves of poorly nourished children (Figs. 16.50 and 16.52).

The difference in percentage rates as determined by the two methods decrease with decreasing time intervals between weighings. Thus, by reducing the intervals between weighings to 5 days, we have: The fetal weight at 13 days, .040 gram; at 18 days, 1.000 grams; hence $R = \frac{1.000 - .040}{.040 \times 5} \times 100 = 480$ per cent; and $k = \frac{\ln 1.00 - \ln .04}{5} \times 100 = 64.4$ per cent per day.

Similarly, for a two-day interval (between 13 and 15 days), Minot's arithmetic method yields 90 per cent, whereas our exponential method yields 51.5 per cent per day.

²⁴ Univ. Mo. Agr. Exp. Sta. Res. Bull. 97, pp. 18-19, 1927.

If a set of data follows an exponential course (eqs. 7, 8, 9), then, knowing the numerical value of k , it is possible to compute the time required for doubling body weight or population size. The time required for a growing body or population to double itself in size is the ratio of the *natural* logarithm of 2, that is, 0.693 . . . to the value of k . The reason for this is given in the following derivation.

Fig. 16.25. Graphic method for evaluating the constants of equations (12) and (14) for a rat. The correct weight value of the mature weight, A , is 350 gms.; if $(350 - W)$ is plotted against age a straight line results. If a larger or smaller value of A is assumed, the curve deviates from a straight line as indicated. The value of B is read from the curve at the point when $t = 0$; $t^* = 1.76$, the age when $(A - W) = A = 350$ gm.

Solve equation (7)

$$\ln W = \ln A + kt \quad (7)$$

for t ,

$$t = \frac{\ln W - \ln A}{k}$$

When the original weight, A , is doubled, W becomes $2A$ and

$$t = \frac{\ln 2A - \ln A}{k} = \frac{1}{k} \ln \frac{2A}{A} = \frac{\ln 2}{k}$$

Fig. 16.26. Graphic method for evaluating the constants for a Jersey cow. A straight line results if A is assumed to be 420 kg, but not 450 or 300 kg; t^* is the age when $A - W = A$, which is 420 kg.

When the percentage growth rate is constant, the time intervals between doubling of weights are constant; therefore, when equation (8) represents growth, the time required for weight to double itself is

$$\frac{\ln 2}{k} = \frac{0.693}{k}$$

Thus, the value of k for fetal growth of the rat was found to be 0.53. Hence, the time required for the rat fetus to double its weight is $\frac{0.693}{0.53} = 1.3$ days; if growth in weight is taken as an index of the increase in the number of cells in the body, then a new generation of cells is produced, on the average, once in 1.3 days; or the cell-division frequency is approximately $\frac{1}{1.3} = 0.77$ per day. It would thus be possible to determine the mean life

of a mother cell before it divides into two daughter cells, if increase in weight were a measure of increase in the number of cells in the body.

Let us next apply systematically this method of computing instantaneous percentage growth rates to the analysis of the self-accelerating phase of several other age curves of growth in weight or population size.

Fig. 16.27. The smooth curve represents equation (12) or (13) for the cow represented in Fig. 16.26. The significance of the constants is indicated graphically.

16.4: The principle of mass action and the self-accelerating phase of growth.

The first principle in biology is that there is within living substance a condition of internal pressure tending toward expansion of self or kind . . . the tendency to take in and assimilate everything assimilable . . . to grow, to multiply. *R. E. Coker*

As explained in the preceding section, the age curve of growth is sigmoid in form (Fig. 16.5) consisting of a self-accelerating phase of increasing slope and a self-inhibiting phase of decreasing slope. The two are joined during puberty in animals, flowering in plants, and "coming of age" in populations of organisms. Let us rationalize the segment of increasing slope with the aid of the principle of mass action.

According to this principle as it is employed in chemistry, the speed of a chemical reaction is, in the simplest case (reaction of the first order), and when other conditions are equal, proportional to the number of available units

(molecules, ions, etc.) entering into the process at the given instance. This principle, then, involves the conception of constancy of percentage rate. It is the principle of compound interest, with the "interest added to the capital continuously from moment to moment", rather than annually, semi-annually, or quarterly as is financially common.

Fig. 16.28. A straight line form of the growth curve. $100(1 - \frac{W}{A})$ was plotted against age on arithlog paper. The Holsteins attained 80 per cent of their mature weight at 34 months, Jerseys at 28 months.

Equation (5)

$$\frac{dW}{dt} = kW \quad (5)$$

and its integrated form

$$W = Ae^{kt} \quad (8)$$

are thus essentially the equations of the physical chemist for the kinetics of monomolecular change. The time curve of early growth, of biosynthesis, is,

as might be naturally expected, similar to that of chemical reactions in general. This statement does not at all imply that growth is a "simple monomolecular chemical reaction", or that it is even limited by such a reaction. It merely calls attention to a similarity in general plan, to a general analogy. The principle of mass action is applicable to the multiplication rate of any category of reproducing units whenever the reproduction rate tends to be directly proportional to the number of reproducing units. Thus when other conditions are equally favorable, one bacterium divides into 2, 2 to 4, 4 to 8, and so on in a geometric progression.

Fig. 16.29. The relation between the mature weight, A , and the speed of approach to the mature weight during the self-retarding phase of growth.

The term k in equation (8) is the velocity constant of the physical chemist, or the (instantaneous) growth rate (relative rate, or percentage rate when multiplied by 100) of the biologist.

Equation (8) may be fitted to data by the method of least squares or graphically. In either case, it is first "rectified", *i.e.*, written in linear form, by taking logarithms of both sides:

$$\ln W = \ln A + kt \quad (7)$$

which has the same form as the linear equation $y = a + bx$

$\ln W$ corresponding to y , $\ln A$ to a , and kt to bx .

Therefore, if the logarithms of W (weight) are plotted against the corresponding values of t (age), a straight line results of slope k , and intercept $\ln A$, and the equation is thus fitted graphically to the data.

Since the eye is sensitive to deviations from a straight line, it is easy to judge whether equation (7) represents the course of change. Whenever the equation fails to represent the data, notice is registered by deviation from the straight line.

Instead of plotting logarithms, the original data may be plotted on arithlog paper, the vertical axis of which is divided logarithmically and the horizontal axis arithmetically. We shall use this method because it saves the labor of looking up logarithms and keeps before us the meaningful original data instead of logarithms, which are vague to most of us.

Fig. 16.30. Relative speeds of approach to the mature weight of albino and Norway rats. Both are plotted in terms of the percentage of mature weight. One month in the albino rat is equivalent in speed of approach to mature weight to 3.3 months in the Norway rat. The upper curves represent albino rats respectively of Donaldson and of Greenman; the lower curve represents Norway rats of King.

The fact that the paper is divided on a decimal scale gives the slope, k , of equation (7), a value in terms of common logarithms. This value is converted into natural logarithms by dividing the observed slope by 2.3 ($\ln 10 = 2.302 \dots$).

The equation may be fitted by the method of least squares (appendix to Ch. 13), but only after the data have been plotted on arithlog paper to ascertain that there are no breaks in the curve and that the distribution of the data on the arithlog grid is linear. Equation (7) may be fitted only to data distributed linearly on the arithlog paper.

Fig. 16.10 shows the same (Stotsenburg) rat-growth data on arithlog paper (upper left) and also on arithmetic paper (lower right). The arithmetic curve

has an increasing slope. The curve drawn through the arithlog curve has a constant slope, k . Equations (7) or (8) thus represent satisfactorily the course of growth of the rat fetus from 14 days after conception to birth, and the instantaneous growth rate is constant—53 per cent per day as given by the equation fitted to the data

$$W = .000065e^{0.53t}$$

If this reasoning is sound, we have reached the important conclusion that the instantaneous percentage growth rate remains constant during the physiologically enormous period from 14 days after conception to birth:

Fig. 16.31. Relative approach to the mature weight of rats on normal diets (numbers 3, 4, 5, and 6) and "maximum-growth" diets (numbers 1 and 2). Curve 1 represents rat 3414 of Osborne and Mendel, curve 2, the average of rats B2135, B2132, B2164, B2161, B3380, B3432, B3414, B3441, B581, B693, B1978, B1974, B2264, B226, B3218 raised on improved diets described in *J. Biol. Chem.*, **69**, 668, (1926). Curve 3 represents Osborne and Mendel's 1925 averages. The points connected by broken curves in Fig. 16.31 represent 98 per cent of mature weight.

The instantaneous percentage growth rate during the 10 days following birth is only about 12 per cent; but it is constant, which is the essential new fact. The constancy of percentage growth rate during the first 10 postnatal days is also indicated in Fig. 16.11, in which the values of $100k$, for 3 sets of rats, are plotted against age; the resulting curves are horizontal, that is, the percentage rate of growth is practically constant. The break in the curve at birth is, among other factors, associated with a radical change in the mode of life.

In Fig. 16.12 the data during the first 10 days following birth are plotted again, together with the remaining data for the phase of growth preceding the inflection. From conception age 32 days (10 days after birth) to 52 days, the instantaneous growth rate appears to be 4 per cent per day; from 52 days up to the inflection (about 85 days after conception, 65 days after birth) 3 per cent per day. (We are not certain of the presence of later breaks.)

The breaks are also illustrated in the increment curve²⁵ of Fig. 16.13. The conclusion is, then, that while the percentage growth rate declines with age, the decline is much slower than has ever been thought before, and the decline does not appear to be continuous. The percentage growth rate remains relatively constant between rather wide limits, and then declines relatively abruptly to a new low level.

Fig. 16.32. See legend for Fig. 16.31.

Figuratively speaking, the medium in which the body cells grow has buffer properties analogous to those of body fluids against acid or alkali. When, for example, acid is added to blood, the blood pH remains constant because of its buffer properties (Ch. 10). It is only after a certain fraction of the buffer is "spent" that the acidity exceeds a certain threshold, or critical value, and affects the welfare of the organism. May not an analogous situation exist with respect to the growth-retarding substances in the body?

²⁵ Weight increments increase at the same percentage rate, $100k$, as the body weight itself.

Indeed, this appears to be the situation for growth of a population of lactic-acid producing organisms in milk, measured by the rate of accumulation of lactic acid in milk, as shown in Fig. 16.14. Neutralizing the lactic acid in the milk is followed by a new cycle of exponential growth (Fig. 18.1).

Fig. 16.15 shows the constancy in the percentage growth rate of *B. coli* (also an acid-producing organism) in broth. This constancy in the percentage growth rate of acid-producing bacteria is due to the high buffer value of the medium, which neutralizes the growth-retarding lactic acid as it is produced, thus keeping the culture in the same state for a relatively long period. When the threshold pH is exceeded, the percentage growth rate declines.

A similar situation prevails in human population growth. When the density of the population is very low during its early history and much more fertile land is available than the population can utilize, the natural increase of the human population occurs at a constant percentage rate. This is illustrated by Figs. 16.16 and 16.56 for the growth of the American Colonies and United States population. This population grew at the instantaneous rate of 2.9 per cent per year from 1660 to 1890. The critical or "threshold value" was reached in 1880, when the growth of the population began to decline (Ch. 25).

Fig. 16.33. Comparison of growth of English children, "laboring" and "non-laboring." Data by Roberts, compiled by B. T. Baldwin, *Univ. Iowa Studies in Child Welfare*, 1, 1 (1921).

Fig. 16.17 represents the percentage growth rate ($100k$) of the rat as a function of age; it indicates the manner of decline in the "growth potential" with increasing age. The graph reminds one of a series of water pipes, each of which is relatively horizontal, has a relatively constant head pressure, and is below its predecessor, finally fading to zero. This is the essential history of a running stream to its ultimate end, and of growth to its ultimate end.

The most striking age curve obtained in this analysis of early growth is shown in Fig. 16.18a, which relates CO_2 production with age in the chick embryo. The age increase in CO_2 production is perhaps a better index of growth than the age increase of weight, since weight increase may be due to increase in relatively inert, or even non-living, matter whereas CO_2 production represents definitely living, metabolizing tissue.

We prepared Fig. 16.18a from data by Atwood and Weakley.²⁶ Each egg was incubated individually in a glass tube. The data points represent the average daily CO_2 output of the 63 eggs which hatched normal chicks. The circles represent observed values. The relatively high CO_2 output during the first day in comparison to the second is apparent only because the eggs were kept, as is customary, in a cool cellar before incubation. When, therefore, the eggs were subjected to the relatively high incubator temperature, there was in addition to the metabolic CO_2 output an expulsion of the excess

Fig. 16.34. The data in Fig. 16.33 in terms of percentage of mature weight, including data on growth in height.

CO_2 because of its lower solubility at the incubator temperature. This explanation is substantiated by the data for the CO_2 excretion of a control, infertile, egg represented in Fig. 16.18a by crosses. The CO_2 production during the first day is virtually the same for the control and incubating egg. The CO_2 production associated with incubation is properly represented by the difference between the fertile and infertile control.

The distribution of this difference between the CO_2 production of fertile and infertile eggs is fairly linear on the arithlog grid: the instantaneous increase in CO_2 production *during the first four days of incubation* is seen to be of the order of 100 per cent per day. It is interesting to note that the cleavage

²⁶ Atwood, H., and Weakley, C. E., W. Virginia Agr. Exp. Sta. Bull. 185, 1924.

rate of the rabbit and rat eggs during the first three days of incubation (Fig. 16.2) is of the order of 120 (rat) to 140 per cent (rabbit) per day.

Fig. 16.19 illustrates in a more striking manner the drop in CO_2 production during the second day. Here the percentage increases, $100 (\ln W_2 - \ln W_1)$, were plotted against age. The greater drop in Bohr and Hasselbalch's curve is probably due to a lower preincubation temperature than in Atwood and Weakley's.

Fig. 16.35. Relative approach to maximum milk yield under Advanced-Registry test and ordinary conditions of management. The better-fed test animals approach the mature level at a more rapid rate.

Returning to Fig. 16.18a, from 4 to 15 days the data points are distributed in a remarkably uniform manner around a straight line, indicating an instantaneous increase of .31 per cent per day. The second remarkable feature of this graph is the pause between 16 and 19 days. The chick no doubt passes a critical period, a "metamorphosis", at this stage. This statement relating to a critical period is substantiated by the mortality curve, Fig. 16.20, which passes a peak at this time. The trigger mechanism in the break may be a change in the mode of respiration: the respiratory function is transferred from the chorioallantoic membrane to the lungs; the chick "metamorphoses" from an aquatic to a terrestrial mode of respiration.

The smaller peak in the mortality curve at about five days may perhaps be correlated with the peak in the lactic-acid curve shown in Fig. 16.20. The mechanism of lactic-acid oxidation apparently does not begin to function efficiently until this time.

Fig. 16.21 represents data of Hasselbalch and of Murray. The distribution of the data points is less regular because of the smaller number of embryos.

Fig. 16.36. Relative lactation slopes for Jersey cattle.

These charts do not show the last stages of growth; otherwise, the general features of the charts are the same. The values of k for the data of Hasselbalch are the same as those for the data of Atwood and Weakley. The value of k for Murray's data is higher, but this is probably due to a higher incubation temperature. Fig. 16.18b, which represents the age curve of nitrogen storage in the silkworm embryo, is remarkably similar in respect to the growth pause to the age curve of CO_2 excretion in Figs. 16.18a and 16.21.

Fig. 16.22 represents the growth of the fowl during 12 weeks of postnatal life. There appears to be a break in the curve at 3 weeks. The major inflection occurs at the age of about 12 weeks. The values of k during this period are of the same order as those found for the rat.

Humans have a very slow prenatal growth rate in contrast to other species. While the instantaneous prenatal growth rate in the rat is about 53 per cent per day (Fig. 16.10), that of man²⁷ ranges from a maximum of 8 per cent to a minimum of 1.3 per cent per day (Fig. 16.23b). Therefore, given percentage rates of growth do not indicate equivalent developmental stages. It was already noted (Fig. 16.7) that the age curve of man is distinguished from those of other species by a very long juvenile period. Fig. 16.24 shows that growth during the juvenile period is about 10 per cent per year, that is, only 0.83 per cent (10/12) per month or 0.03 per cent (0.83/30) per day.

Fig. 16.37. Relative lactation slopes of Guernsey cattle.

16.5: Extension of the principle of mass action to the self-inhibiting phase of growth

The same path leads up the hill and down. *Heraclitus*

I rise again, changed but the same. *Jacques Bernoulli*

The great object in life of an oyster is to convert the whole world into oysters. The biotic potential of the oyster is limited more by the outside forces than by its own lack of biotic ambition. *R. E. Coker*

²⁷ Streeter, G. L., Carnegie Institution of Washington, Contributions to *Embryology*, 11, 143 (1920).

As previously explained, the age curve of growth may be divided into a self-accelerating phase of increasing slope and a self-inhibiting phase of decreasing slope. During the self-accelerating or unrestricted phase, the time rate of growth tends to be proportional to the size of the individual or of the reproducing population. However, this geometric increase cannot go on

Fig. 16.38. Relative lactation curves of Holstein cattle.

indefinitely because of the restricting limitation of the universe. Each lives under a condition not only of pressure from within, tending toward expansion of self or kind to multiply and fill every occupiable niche, but also under a pressure from without which keeps expansive pressure under control.²⁸

Mention was made of the restrictive effect of the population increase of *Drosophila*, yeast bacteria, on further increase of the population. Analogous restrictive effects may contribute to decline in growth rate of multicellular animals in later growth stages. For instance, the decrease of the ratio of

²⁸ Coker, R. E., *Scientific Monthly*, 48, 61, 121 (1939).

surface to body weight during growth²⁹ results in progressive congestion in the transportation of nutrients and wastes. One may also mention progressive interference with the transportation of nutrients and wastes through progressive accumulation of inert materials in the body and progressive dehydration and decline in permeability.

The mass law equation for the self-inhibiting phase of growth may be formulated just as for the self-accelerating phase, with this difference: during the self-accelerating phase, the growth rate, dW/dt , is proportional to the size of the population or to that of the multicellular individual; during the self-inhibiting phase it is proportional to available "living space", available land,

Fig. 16.39. Growth of dairy cattle.

available food supply, available freedom from the deleterious products of growth, and so on. These ideas may be formulated in the conventional terms of the physical chemist, with the symbols used for the self-accelerating phase of growth.

²⁹ Cohn, A. E., and Murray, H. A., Jr., *Quart. Rev. Biol.*, **2**, 469 (1927).

Let A represent the limiting food required to attain maximum individual or population size, and W the food supply at the given time; $(A - W)$ then represents the concentration of the limiting food supply at the moment just sufficient to permit attainment of maximum individual or population size.

It is reasonable to assume that the instantaneous growth velocity, dW/dt , at the given time will be proportional to the concentration of the limiting food supply, that is, to the value $(A - W)$

$$\frac{dW}{dt} = -k(A - W) \quad (9)$$

Fig. 16.40. Growth of Horses.

Instead of food, the growth-limiting factor in the environment may be some growth product, as lactic acid to growing lactic-acid bacteria in milk, or alcohol to alcohol-producing yeast in fruit juice. Let A be the concentration of lactic acid or alcohol suppressing completely the growth force residing in the cells, and W its concentration at the present time. Then, as before $(A - W)$ represents the amount of growth which the environment will permit in order to bring the population to the maximum size, A , and $\frac{dW}{dt} = -k(A - W)$, the instantaneous velocity of growth at the given time. Analogous reasoning applies to the growth of multicellular animals, which are cell populations, after all.

The numerical values of the constants are estimated as follows: A , which represents the concentration of the growth-limiting factor when growth is completely inhibited, may be used to represent the mature weight of the animal (or the maximum size of the population) under a given set of conditions; W may be used to represent the weight of the animal (or size of the population) at the given time; $(A - W)$ then represents the amount of growth yet to be made to reach the mature weight.

Although equation (9) appears to differ from equation (5), both represent the mass law (for a first-order process); both represent a direct proportionality between growth velocity, dW/dt , and some growth-limiting factor. In equa-

Fig. 16.41. Growth of Sheep.

tion (5) the growth-limiting factor is W , the growth already made; in equation (9) it is $(A - W)$. In equation (5), k is the relative growth rate with respect to the growth already made,

$$k = \frac{dW/dt}{W} \quad (5)$$

while in equation (9) k is the relative growth rate with respect to the growth yet to be made

$$-k = \frac{dW/dt}{A - W} \quad (9)$$

Before applying equation (9) to data, it is integrated, for reasons explained in the preceding section:

$$dW/dt = -k(A - W) \quad (9)$$

$$\frac{dW}{A - W} = -kdt$$

$$\ln(A - W) = -kt + \ln B \text{ (integration constant)} \quad (10)$$

$$A - W = Be^{-kt} \quad (11)$$

$$W = A - Be^{-kt} \quad (12)$$

The significance of the constancy of the exponent k is that the growth velocity declines at a constant percentage rate $100k$, illustrated by the following numerical example.

Fig. 16.42. Growth of Swine.

The average increase in weight of guinea pigs in successive months during the self-inhibiting phase of growth was observed to be

$$112, 90, 70, 56, 45, 35, 27, 21 \dots \text{gms.}$$

The instantaneous relative decline in growth rate was, therefore, in round numbers,

$$\frac{112 - 90}{112} = \frac{90 - 70}{90} = \frac{70 - 56}{70} = \frac{56 - 43}{56} = 0.22, \text{ or } 22 \text{ per cent per month.}$$

Just as $100k$ represents the percentage *decline* in growth, so $100p$ represents the percentage *persistence* of growth. Thus in the above example for guinea pigs which gained in successive months

$$112, 90, 70, 56, 45, 35, 27, 21 \dots \text{gms.}$$

the *persistence* of growth is

$$\frac{90}{112} = \frac{70}{90} = \frac{56}{70} = \frac{43}{56} = \frac{35}{43} = \frac{27}{35} = \frac{21}{27} = \dots = 0.78 \text{ or } 78 \text{ per cent per month.}$$

It is obvious that the sum of the percentage decline and percentage persistency of growth must equal to 100 per cent

$$78 \text{ per cent} + 22 \text{ per cent} = 100 \text{ per cent}$$

The minus sign of k in equation (9) indicates a decline in growth velocity.

The fit of equation (12) to growth data may, as before, be ascertained by the graphic method. The logarithmic form (equation 10) is used for this purpose. ($A - W$) is plotted against age, t , on arithlog paper. A straight line results if the proper value of A is chosen, and if the equation represents the data. Several values of A are chosen, and $A - W$ plotted. There is an upward curvature for high values of A , a downward curvature for low values of A , and linear distribution for the correct value of A .

Fig. 16.43. Growth of Rabbits (Castle).

This method of fitting the equation is illustrated in Figs. 16.25 and 16.26. The data points seem to be distributed around a straight line in a satisfactory manner if a correct value of A is chosen. Growth curves drawn according to equations (12) and (14) corresponding to Fig. 16.26, are shown in Fig. 16.27. The agreement between observed and computed values appears satisfactory (of course this applies only to the phase of growth following the inflection).

The value of k is determined by measuring the slope on the arithlog paper (Figs. 16 and 16.26) as was done for the self-accelerating phase of growth. B is the intercept the curve on the arithlog chart; that is, the value of ($A - W$) when $t = 0$. B may,

course, be evaluated algebraically

$$A - W = Be^{-kt} \quad (11)$$

$$\therefore B = \frac{A - W}{e^{-kt}} = (A - W)e^{kt}$$

The constant B may be dispensed with. It is merely an age-parameter (integration constant) employed to correct for the fact that while age is counted from birth or con-

F, Arequipa × Race B, ♂, A = 1.300, k = -.198, t* = 2.05
F, Arequipa × Race B, ♂, A = 1.040, k = -.209, t* = 1.63
F, Cutleri × Race B, ♂, A = .930, k = -.274, t* = 2.00
Wright's data, ♂, A = .810, k = -.249, t* = 2.10
Race B, ♀, A = .800, k = -.247, t* = 2.60
F, Cutleri × Race B, ♀, A = .785, k = -.261, t* = 1.80
F, Cutleri × Race B, ♀, A = .590, k = -.405, t* = 2.22
Cutleri, ♂, A = .400, k = -.529, t* = 2.74
Cutleri, ♀, A = .333, k = -.434, t* = 1.95

Fig. 16.44. Growth of guinea pigs (Castle).

ception, equation (12) fits the data only during the phase of growth following the inflection. This correction may be made in the exponent. The $(A - W)$ curve on the arith-log paper (Figs. 16.25 and 16.26) is extrapolated and the value is read at the point where $(A - W) = A$, that is, when $W = 0$. This is the position at which the extrapolated curve of equation (12) meets the age-axis. By beginning to count age from this point designated by t^* , equation (12) is changed to

$$W = A - Ae^{-k(t-t^*)} \tag{13}$$

since when $t = t^*$, $A = B$.

Equation (13) may be made more elegant by writing it in the form

$$\frac{W}{A} = 1 - e^{-k(t-t^*)} \tag{14}$$

Fig. 16.45. Growth of rats.

which indicates that the fraction of the mature weight, W/A , is a function of the product of the velocity constant, k , and the age as counted from t^* .

When B is known, t^* may be computed as follows:

When $t = t^*$, $W = 0$; therefore

$$0 = A - Be^{-kt^*}$$

$$\ln A = \ln B - kt^*$$

$$A = Be^{-kt^*}$$

$$t^* = \frac{\ln B - \ln A}{k} \quad (15)$$

Fig. 16.46. Growth of rats.

It is often desirable to know the ages when given weights, or given fractions of the mature weights, are reached. These may be determined as follows:

$$A - W = Be^{-kt} \quad (11)$$

$$\ln(A - W) = \ln B - kt$$

$$kt = \ln B - \ln(A - W)$$

$$\therefore t = \frac{\ln B - \ln(A - W)}{k} \quad (16)$$

Fig. 16.47. Growth of mice.

A further simplification may be introduced. Assuming that it is desired to determine the age when some fraction, such as 90 per cent of the mature weight, is reached, W may be replaced by $0.9A$, and equation (16) becomes

$$t = \frac{\ln B - \ln(A - 0.9A)}{k}$$

$$= \frac{1}{k} (\ln B - \ln 0.1A)$$

or in general,

$$t = \frac{\ln B - \ln\left(1 - \frac{W}{A}\right)}{k} \quad (17)$$

For linear growth B may have the same numerical value as A , and equation (12) becomes

$$W = A - Ae^{-kt} = A(1 - e^{-kt}) \quad (12a)$$

Fig. 16.48. Growth of pigeons, doves (Riddle) and rats.

Equation (12a) offers a simpler method of determining the weight at a given age. From (12a)

$$\begin{aligned} \frac{A - W}{A} &= e^{-kt} \\ \ln \frac{(A - W)}{A} &= -kt \\ t &= -\frac{1}{k} \ln \frac{(A - W)}{A} = -\frac{1}{k} \ln \left(1 - \frac{W}{A}\right) \end{aligned} \quad (17a)$$

Equation (17a) shows that, when the value of k is known, one can easily determine the age at which a given fraction of the mature weight is reached. Thus if it is desired to determine the age at which half of the mature weight is reached, W is replaced by $0.5A$, and

$$t = -\frac{1}{k} \ln \left(1 - \frac{0.5A}{A}\right) = -\frac{1}{k} \ln 0.5 = \frac{0.69315 \dots}{k}$$

In a similar manner, the age when any other fraction of the mature weight is reached may be found by substituting the desired value in equation (17a). The following table, in which a series of numerical values of natural logarithms of $\left(1 - \frac{W}{A}\right)$ are given, facilitates numerical computations.

Equation (14) may similarly be used for evaluating the age when a desired fraction of the mature weight is reached.

Fig. 16.49. Growth of domestic fowl.

$$\frac{W}{A} = 1 - e^{-k(t-t^*)} \quad 1 - \frac{W}{A} = e^{-k(t-t^*)} \quad (14)$$

$$\ln \left(1 - \frac{W}{A} \right) = -k(t - t^*) \quad t = t^* - \frac{1}{k} \ln \left(1 - \frac{W}{A} \right) \quad (18)$$

t is easily determined when k and t^* are known. Thus if it is desired to find the age, t , when half of the mature weight is reached, W is replaced by $0.5A$:

$$t = t^* - \frac{1}{k} \ln 0.5 = t^* + \frac{0.69315}{k}$$

Fig. 16.50. Growth of children preceding puberty (16.50) and following puberty (16.51). Note the considerable differences in mature weights and in the shape of the age curves in these figures as also in Figs. 16.52 to 16.54, probably due to differences in environmental conditions.

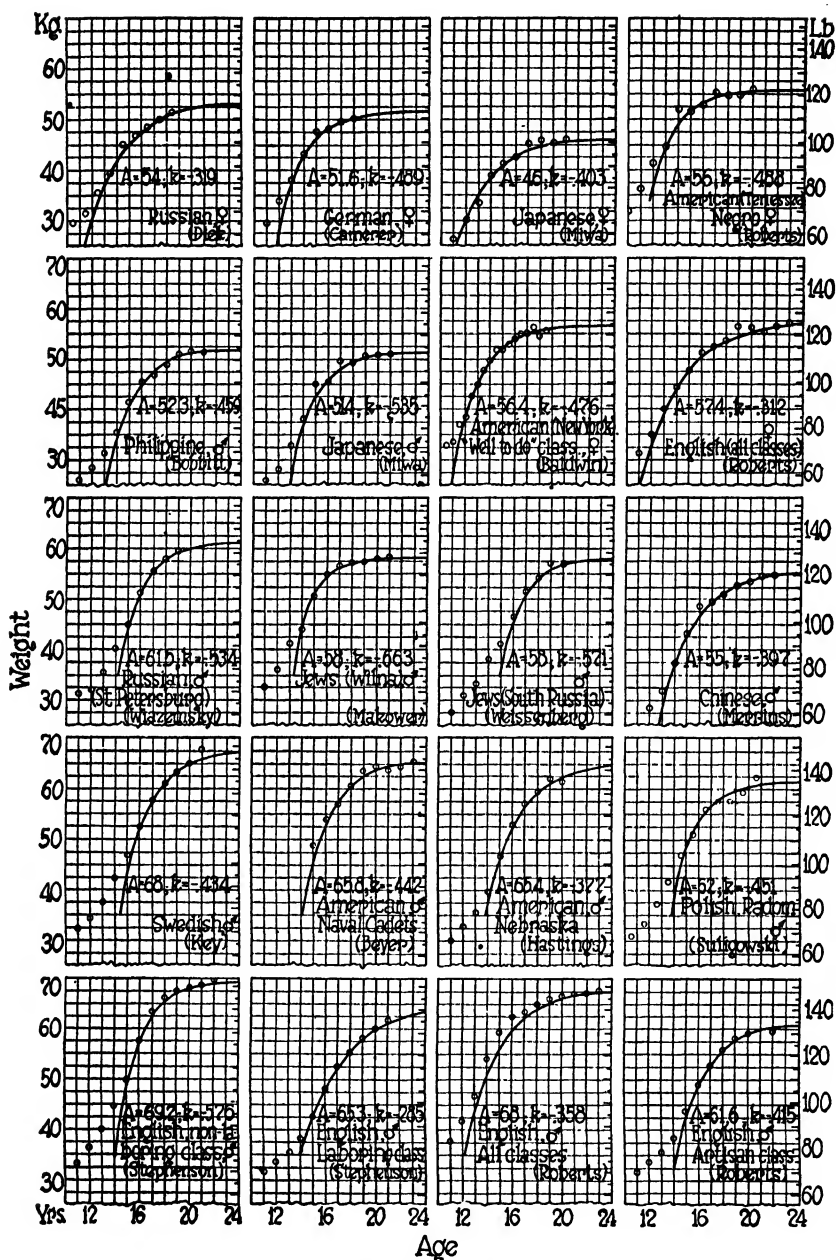

Fig. 16.51. See legend for Fig. 16.50.

Chart for boys

Chart for girls

Fig. 16.52. The juvenile course of growth of children (same data as in Fig. 16.50) plotted on an arithlog grid. It appears that the "pubertal acceleration" represents compensating growth in children who were relatively under nourished during the earlier years, because Fig. 16.52 indicates that the lower the value of k (percentage growth rate) the greater the pubertal acceleration.

The following transformation of equation (14) gives a straight-line function for the growth curve. Transforming

$$1 - \frac{W}{A} = e^{-k(t-t^*)}$$

$$\ln \left(1 - \frac{W}{A} \right) = -k(t - t^*)$$

Fig. 16.53. A comparison of growth curves of children, males, during the post-pubertal period.

This means that plotting values of $\left(1 - \frac{W}{A} \right)$ (which is the fraction of growth yet to be made to reach the mature weight) against age t or $(t - t^*)$ on arithlog paper results in a straight line having the slope k . Fig. 16.28 illustrates the method. This derivation could be foreseen in connection with the method of evaluating A , which consisted in plotting $(A - W)$ against age. This method merely places the curve on a percentage basis.

k (and also B) may be determined from the curve obtained by plotting the velocities of growth against age.

$$W = A - Be^{-kt} \quad (12)$$

$$\frac{dW}{dt} = kBe^{-kt} = Ce^{-kt}$$

$$\ln \frac{dW}{dt} = \ln kB - kt.$$

Hence, plotting the velocities $\frac{dW}{dt}$ (or in practice the successive increments per unit time) against the corresponding ages on arithlog paper will result in a straight line having the slope k . This method is inferior to plotting $(A - W)$ against age on account of fluctuations due to experimental errors.

The fact that the numerical value of the velocity constant, k , is the same in the differential and integral equations makes it possible to derive equation (12) from a knowledge of growth velocities (*i.e.*, gains in weight per unit time at successive ages).

$$W = A - Be^{-kt} \quad (12)$$

$$\frac{dW}{dt} = kBe^{-kt} = Ce^{-kt}$$

Fig. 16.54. Growth curve of children, females, during the post-pubertal period.

Integrating the last equation,

$$W = \frac{Ce^{-kt}}{k} + A \text{ (integration constant).}$$

$$\text{When } t = \infty, W = A.$$

$$\text{When } t = 0, W = A - \frac{C}{k} = A - B.$$

Therefore

$$W = A - Be^{-kt} \quad (12)$$

Thus it is possible to begin with equation $\frac{dW}{dt} = Ce^{-kt}$

in place of

$$\frac{dW}{dt} = k(A - W)$$

and obtain the same result.

For other properties of the growth equation, see Chapter 19.

Fig. 16.55a. Growth of the human brain in weight, W , and in frequency, f , of brain potentials (or alpha frequency or alpha waves, or Berger rhythms). The value of $-k$ (decline in the relative growth rate) is -0.468 for the alpha waves and -0.485 for brain weight (i.e., 48.5 per cent per year); the mature values, W_A and f_A are 1333 gm. for the brain and 10 for the alpha waves. Since $\frac{W}{W_A} = \frac{f}{f_A} = W = f \frac{W_A}{f_A}$; that is, the brain weight, W , is 133.3 times the alpha wave frequency, f (Weinbach).

Summarizing this discussion, prior to puberty in animals, flowering in plants, and "coming of age" in populations, the growth rate tends to be proportional to the growth already made, indicated by the equation

$$\frac{dW}{dt} = kW \quad (5)$$

$$W = Ae^{kt} \quad (8)$$

Following this age growth rate tends to be proportional to the growth yet to be made

$$\frac{dW}{dt} = -k(A - W) \quad (9)$$

$$W = A - Be^{-kt} \quad (12)$$

Fig. 16.55b. The equivalence chart between brain and wave frequency shows their excellent correspondence. Courtesy of A. P. Weinbach, *Growth*, 2, 247 (1938).

[The numerical value of k in equation (9) or (12) is, of course, different and has an opposite sign from the k in equation (5) or (8)].

Animals rapidly attaining the maximal body weight, A , have a high slope, k , as in equations (9) or (12); those attaining it slowly, have a low slope, k . The value of k for given guinea pigs is 0.22; for cattle, which approach mature weight much more slowly, the value of k is much lower, 0.04; for mice, approaching the mature weight much more rapidly, k is much higher, 0.71; and so on.

16.6: Genetic growth constants. The value of A (mature weight) and of the slope, k , on the growth curve are intrinsic or genetic characteristics of the animal under given environmental conditions, in the same sense that the equilibrium and velocity constants of a chemical reaction *in vitro* are intrinsic characteristics of the chemical system under given conditions. Growth, like a chemical reaction *in vitro*, is by definition increase in the mass of one component at the expense of another, and the rates of approach to the equilibrium level are analogous. Table 16.1 (appendix) presents numerical values of the intrinsic or genetic growth constants, A , k , and related derived values. Figs. 16.30 to 16.54 present the constants graphically, together with age curves of growth in weight of several animal species.

The charts are for the most part self-explanatory. The values of A (mature weight), k (speed of approach to mature weight during the self-inhibiting

Fig. 16.56a. The growth of the human population in the U.S.A., plotted on semilog paper. The line represents the equation $P = .0842e^{0.029t}$, meaning that the population, P , grows at 2.9% per year (instantaneous basis) or is doubled in 23.4 years.

phase of growth), and t^* (age at which the extrapolated curve meets the age axis) are given for each species. The differences within the species are due mostly to differences in environmental conditions, especially food supply.

Before proceeding with the discussion of the influence of environment on the numerical values of the constant, it is interesting to note that the mature size, A , of different species tends to be related to the growth constant, k , or to the time required to reach a

given percentage of the mature weight (Fig. 16.29 plotted from Table 16.1). As might be expected from the long juvenile period, the data points for man deviate from the general curve. Also, as might be expected, there is considerable scatter of the data because A and k are not influenced by environmental conditions in the same direction and the environmental conditions for the different animals were not the same. Moreover, males, females, and castrates were lumped together in Fig. 16.29. Nevertheless, the index of correlation is relatively satisfactory.

We may begin by pointing to the difference in approach to mature weight in Wistar Norway and albino rats³⁰ (Fig. 16.30). The mature weight is virtually the same in both, but the albinos attained mature weight much earlier. Dr. King informed us that the Norway curves approach the albinos

Fig. 16.56b. Growth of the human population in the U.S.A. showing the increment curve (2) and cumulative curve (1), extrapolated to year 2100.

with successive generations of cage life. Cage life apparently does not agree with first-generation Norway rats.

Figs. 16.31 and 16.32 represent growth curves of albino rats fed on ordinary and "improved" diets. The animals on the "maximum-growth" ration reach the mature size much earlier than the controls. The data for Osborne and Mendel "maximum growth" rats were given the writer by Dr. Osborne during a personal visit. Many published papers from Osborne and Mendel's

³⁰ Data in Donaldson, H. H., "The rat," 1915, 1924 (Wistar Institute, Philadelphia).

laboratory on exceptionally rapid growth of rats³¹ substantiate the curves in Fig. 16.31 and 16.32.

Similar results were observed on other species. Thus, Figs. 16.33 and 16.34 indicate that the average English "laboring" individual appears to be smaller than the average "non-laboring" individual, and that children of the laboring class take longer to reach a given growth stage than those of the non-laboring. This difference may be due in part to differences in environmental conditions.³² This difference in weight-growth rate (see also Figs. 16.50 to 16.54) may partially account for differences in intelligence quotients. It is not unreasonable to assume that mental and physical development are associated.³³

Fig. 16.56c. Percentage increase (1 and 2) in and time required for doubling human population in the U.S.A. (3).

Since the maintenance cost of animals is the largest item in the growth cost, rapid growth and early maturity imply some saving, and therefore increased efficiency not only of growth but also of productive processes (such as milk and egg production, muscular work), since the growth expense is charged to the productive process during maturity. (For exceptions, see Chs. 3 and 18.)

There are similar environmental influences on the maturation speed of physiological functions, such as milk production, illustrated in Figs. 16.35 to

16.38. Advanced Registry dairy cattle receive better care and feed, and they approach their maximum milk yield and weight at an earlier age.

Employing chemical terminology, increasing the effective concentration of the growth-limiting constituents (food) in the system increases the velocity, k , of the process (growth). The growth velocity, k , of the poorly fed rat of Donaldson (Figs. 16.31 and 16.32) is 0.0135, but that of the well-fed rat of Osborne and Mendel is 0.0266; thus the speed of approach to the mature value is twice as great in the rats on the better diet.

Nutritional aspects of growth are discussed in Chapter 20; endocrine aspects, in Chapter 7; seasonal aspects, in Chapter 8; temperature aspects, in Chapter 11.

Fig. 16.57a. Robertson's theoretical autocatalytic monomolecular cycle representing the time rate of gain, dW/dt , as function of time. Note its symmetry about the center. Actual "growth cycles" are not so symmetrical.

Fig. 16.57, from Walton and Hammond,³⁴ is a dramatic illustration of spatial effect on growth—how the size of the mother influences the prenatal size of the offspring. The parents were the giant (1800 – 2400-lb or 800 – 1000-kg) Shire and the dwarf (540-lb or 200-kg) Shetland. The cross foals from the giant mother and dwarf father were three times the size of the cross foals from the dwarf mother and the giant father. The maternal-environmental limitation masked the genetic differences during the prenatal period of growth. After weaning, however, the genetic influence came into its own. The cross foals of the dwarf mothers grew much more rapidly than Shetlands and the growth curves of the two crosses tended to converge to a common mature weight. Byerly³⁵ reported similar results by hybridizing bantam silkies and Rhode Island Red chickens.

16.7: Note on the relation between average and individual growth curves.

A fundamental characteristic of living organisms is that they are alike in general plan and different in detail. There are two corresponding schools of biologists, one of which emphasizes the average and general and the other the individual and particular. The rapid development and diffusion of statistical techniques in the biologic as well as in the physical sciences tends to emphasize average and the general; on the other hand, great discoveries and

³⁴ Walton, A., and Hammond, J., *Proc. Roy. Soc. London*, **125B**, 311 (1938), and in several other publications.

³⁵ Byerly, T. C., et al., *J. Exp. Zool.*, **78**, 210 (1938).

concepts of biology have resulted from scrutiny of the individual, of the detail. Thus the concept of natural selection emphasized differences between individuals; the notion of gene is an individual one; so is the concept of mutation. Both approaches are useful, depending on the opportunities and aims.

Davenport³⁶ investigated the relative significance of individual and average growth curves of children with special reference to the adolescent growth spurt. He found that adolescent growth acceleration is often explosive, occurring at any time between 11 and 17 years. It may be sharp or fluctuating, high or low. Environment could not be the chief factor because great variations were observed between brothers reared in the same home.

Fig. 16.57b. The time course of oxidation of linseed oil under various conditions, a familiar autocatalytic process resembling growth curves.

Davenport believes that the average increment curve not only resembles the Gaussian (probability) distribution curve, but is a Gaussian curve. The peak of the average increment curve is at 14.5 years; individual growth spurts are distributed around this average. The frequency and amplitude of the spurts diminish on each side of the peak. Similar results were reported by Boas,³⁷ Gray,³⁸ and others (Fig. 16.60a). Merrell³⁹ reached a similar conclusion for rabbits. The Pearl-Reed logistic was fitted to individual and average growth curves of rabbits. The average differed in fundamental characteristics from the separate curves. Significant undulations observed in the average were absent in the individual growth curve. Undulations and changes in skewness are often the result of the averaging process, unrelated to the biology of growth. In brief, the growth process in an individual is not the smooth sigmoid curve represented by average curves. The average curve represents properties of the mathematical averaging process often absent in individuals. A considerable literature is being developed on individual growth by the "longitudinal" method consisting of seriatim observations⁴⁰ of the same individuals.

16.8: Growth of the human population in the United States.

In the next 25 years the population of the Island will be 28 million, and the means of subsistence only equal to the support of 21 million. In the next period, the population would be 56 million, and the means of subsistence just sufficient for half that number. *T. R. Malthus, 1798.*

It may be surprising to learn that the growth of the human population has the same shape and may be represented by the same equations as the growth curves of individual animals and of populations of bacteria, yeast, and flies confined to a limited space. Yet this appears to be true, and attention has already been called to this similarity (Figs. 16.4 to 16.5, 16.15 to 16.16, 16.56a to c, and 19.32).

Fig. 16.58. The Verhulst-Pearl-Reed "logistic" growth equation. Compare to Fig. 16.4.

As we have seen, the time curve of growth—of individuals or populations—is composed of a segment of increasing slope and a segment of decreasing slope, with the inflection occurring at a critical period, flowering in plants, puberty in animals, and the end of a "free frontier" or some other critical era in population growth. Now Malthus' statement of the tendency of human population—in common with other populations—to increase exponentially, that is in a geometric progression, in this case doubling itself every 25 years, is correct for the period of unrestricted growth, for the segment of increasing slope.

This, indeed, is the history of the population growth in the United States

between 1660 and 1880, as shown in Figs. 16.16 and 16.56. During these 220-odd years the population doubled itself every $23\frac{1}{2}$ years, quite close to Malthus' estimate of 25 years. The rate of this doubling is also shown by Curve 3, Fig. 56c; the doubling curve is quite horizontal, near 25 years between 1660 and 1880; the population increased at the rate of 2.96 per cent—about 3 per cent—per year.

Malthus, however, committed a common extrapolation error in saying that "in the next period, the population would be 56 million". The realization of the inherent tendency to grow, to increase in a geometric progression, at a constant percentage rate, occurs only when the environment does not restrict growth, a condition offered by the United States up until about 1880. Thereafter the expansive urge for geometric-progression increase is held in check

Fig. 16.59a. Growth in weight of cattle.

by environmental limitations. Thus in the United States, closing of the frontiers, closing of the free-land era, shifting of the population from the farm (where wife and children are economic assets) to the city (where they are economic liabilities), increasing the period of education, increasing wants (automobile, radio and other gadgets) may all be considered as environmental limitations. Man is governed by man-made psychological factors—by fashions, if you please—even more than by intrinsic animal urges. Elsewhere, perhaps in India, China, and the Middle East, and so on, starvation and famines hold the population in check. Disease ravages may keep in

check overcrowded populations⁴¹. In the United States and other western-civilized countries, the limitation of the population is not usually caused by famine or plagues, but by more subtle factors, at least among the middle and upper classes sensitized to their operations. The "lower" classes are less attuned to the shifting of economic and psychologic winds and their reproductive pattern is more persistent, more stable⁴²; but they suffer a higher infant mortality⁴³.

Fig. 16.59b. Growth in height of cattle.

The neuro-psychologic sensitiveness of our population to overcrowding recalls Pearl's observations⁴⁴ on the influence of overcrowding of flies, *Drosophila* in a half-pint bottle. All conditions were constantly favorable except the number of insects per bottle.

⁴¹ "Only one out of every five children born in Teheran lives to the age of six . . . The real public health problem, of course, is poverty."—W. L. Willkie, "One World," Simon and Schuster, 1943.

Physiol.*, **45**, 799 (1928), and others.

The effect of density of population upon egg-laying was immediate. . . . The same flies were exposed to conditions of high density in alternating twenty-four hour periods. The rate of egg production per female per day was higher in the low-density periods than in the high. The view is developed . . . that crowding produces the observed effect on rate of egg laying primarily . . . as a result of a collision or interference action of the flies upon each other, which alters the normal physiologic equilibrium and processes of the individual, particularly with reference to three major functions—food intake, energy input in muscular activity, and oviposition.

We see here the operation of an elegantly delicate homeostatic mechanism for holding the population in check not involving the crude, cruel, ravages of starvation, disease, and attack of enemies, as we find under natural conditions.

Fig. 16.59c. Weight increments in growing cattle.

It appears that the shape of the growth curve of United States population, especially of the more sensitive middle and upper classes (Fig. 16.56) is molded not by starvation, plagues, attacks of external enemies but by homeostatic mechanisms psychologic in nature, analogous in delicacy to that operating in the population of *Drosophila* confined in a half-pint bottle in the presence of abundant food, air, and absence of disease and natural enemies.

As previously noted, the situation is different in some human populations, especially in Asia; and even some highly civilized European peoples prefer (consciously or unconsciously) the overflow and war methods of homeostasis for keeping the population in check in accordance with the general law of sigmoid growth.

The overflow method of taking care of surplus population, of the urge to reproduce indefinitely in a geometric progression, is illustrated, on a small scale, in all its terrible drama in the periodic overflow of the lemming,⁴⁵ a species of field mouse. These animals breed in the upper altitudes of Norway, and every 3 to 4 years the population becomes too great for its normal habitat. So it overflows, and following the path of least resistance, migrates down the valley in search of food, finally reaching the sea where it drowns in count-

Fig. 16.59d. Height increments in growing cattle.

less thousands. Folk-lore has it that they migrate for ideological reasons, in search of a sunken Atlantic continent.

16.9: Comparison of our growth equations with some others. The age curve of growth in weight or in cell number when plotted on arithmetic paper consists of (1) a segment of increasing slope, a self-accelerating phase, reflecting predominantly the expansive drive to grow in geometric progression; (2) a segment of decreasing slope, a self-inhibiting phase, reflecting predominantly the back pressure of the environment on the expansive drive.

⁴⁵ Elton, C. S., "Voles, Mice and Lemmings, Problems in Population Dynamics," Oxford, 1942.

During phase (1) the growth rate, dW/dt , tends to be proportional to the growth already made, to the weight, W , of the animal, as given by the equation

$$dW/dt = kW \quad (5)$$

This segment, however, shows several discontinuities or "breaks," analogous to metamorphosis.

During phase (2) the time rate of growth tends to be proportional to the available "living space," to the difference between the present weight, W , and the mature weight, A , as given by the relation

$$dW/dt = k(A - W) \quad (9)$$

Fig. 16.59e. Chest increments in growing cattle.

On integrating the growth increments dW for the corresponding time intervals dt , the weight, W , of the animal is given as function of age, t . For equation (5) the integrated equation is

$$W = Ae^{kt} \quad (8)$$

and for equation (9),

$$W = A - Be^{-kt} \quad (12)$$

The numerical values of k have definite physical meanings: $100k$ is the percentage growth rate with respect to the growth already made (weight of the animal) in equations (5) and (8) and with respect to the growth yet to be made in equations (9) and (12). (Another physical definition of k : in equation (5), $dW/dt = k$ when $W = 1$; in equation (9), $dW/dt = k$ when $A - W = 1$.)

Special emphasis is placed on the fact that equations (5) and (9) do not represent growth rate as explicit functions of time, but of the condition of the growing system itself. Time is merely a frame of reference (Chs. 10 and 19) introduced as matter of convenience during the integration process.

Most other equations in the literature, on the contrary, represent growth rate as an explicit function of time. Thus the Pearl-Reed⁴⁶ logistic equation is

$$dW/dt = k_1t + k_2t^2 + k_3t^3 + \dots).$$

Likewise the Glaser⁴⁷ equation is

$$dW/dt = k \frac{1}{2t + 1} W, \text{ or } \log W = k \log (2t + 1) + c$$

(The Glaser equation indicates that the percentage (or logarithmic) gain between, for example, the fifth and sixth day of growth of the chick embryo is proportional

Fig. 16.59f. Increment of hip-width in growing cattle.

to $\frac{1}{6^2 - 5^2} = \frac{1}{11}$, and so on for each successive day; it is proportional to the difference between the squares of the final and initial age intervals. In equation form it may be written $\frac{dW}{dt} = \frac{KW}{2t}$ or $\log W = \frac{K}{2} \log t$, or $\log W = k \log (2t + 1) + c$, in which $k = \frac{K}{2}$.)

The MacDowell-Murray-Schmalhausen equation⁴⁸

$$\log W = k \log (t - n) + c$$

is in principle identical with the Glaser equation.

⁴⁶ Pearl, R., and Reed, L. J., *Metron*, **3**, 1 (1923), and many other papers.

⁴⁷ Glaser, O., *Biol. Rev.*, **13**, 20 (1938), and *Growth*, Supplement, p. 53 (1940).

⁴⁸ MacDowell, E. C. and C. G., Gates, W. H., and Allen, E., *J. Gen. Physiol.*, **11**, 57 (1927), and **13**, 529 (1930). Murray, H. A., Jr., *Id.*, **9**, 39 (1925). Schmalhausen, I., *Arch. Entwicklungsmech. Organ.*, **110**, 33 (1927), and **124**, 82 (1931).

These equations seem to be illogical because they are explicit functions of time rather than, as our equations (5) and (9), functions of the condition of the system itself.

It is natural to assume that time is an element of the growth process because growth is correlated with time. But it is well known that by appropriate experimental procedure, the growth process may be delayed or accelerated, whereas time, of course, con-

A = average; E = early maturing; L = late maturing.

tinues to flow at a uniform rate. Thus, Osborne and Mendel succeeded in arresting the growth process in the albino rat from the age of about 2 to 17 months; then when the animals were placed on an adequate diet, growth was resumed at a rate which was characteristic of the species for the given weight, and not for the given age. This statement is substantiated by the excellent fit of equation (9) or (12) to the data of Osborne and Mendel as shown in Fig. 19.16.

The above MacDowell-Murray-Schmalhausen equation shows that the logarithms (or percentages) of size vary directly with the logarithms (or percentages) of time. It is logical to assume that the number of cells increases logarithmically, that is, in geometric progression; but it does not seem logical to assume that time flows logarithmically.

We have been criticized for assuming the presence of discontinuities, "breaks," in the age curve of growth during the self-accelerating phase. But the critics' equations likewise represent only limited segments of the curve. The presence of discontinuities in the growth curve was also substantiated directly by Lerner,⁴⁹ Romanoff,⁵⁰ and others.

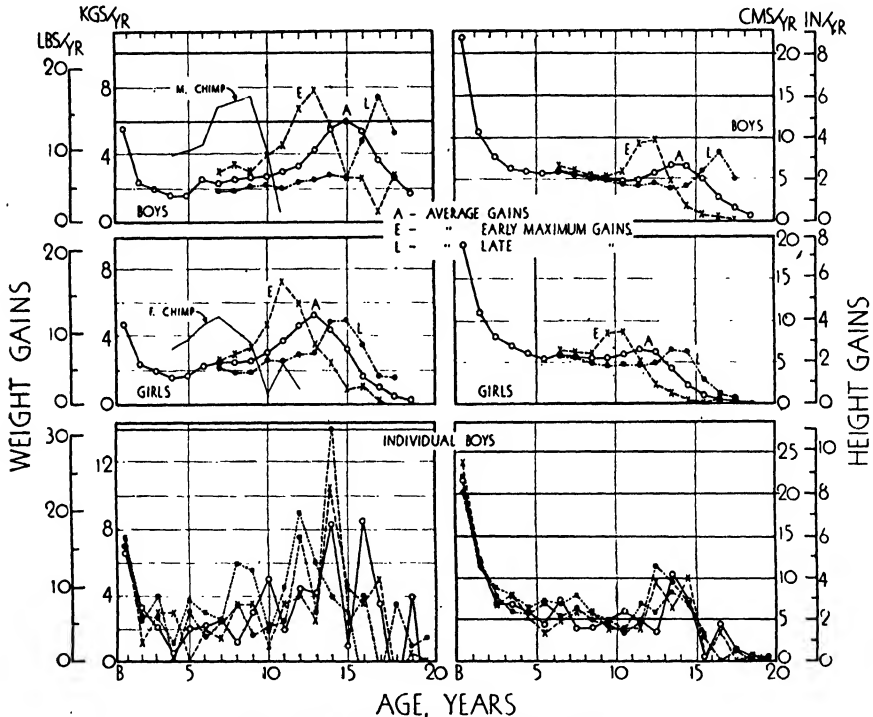

Fig. 16.60b. See legend for Fig. 16.60a

It is illogical to object to the presence of relative discontinuities in the growth curve when their presence in the individual (metamorphoses, most conspicuously in cold-blooded animals) and in the race (emergent evolution) are generally known. When external conditions are equal, growth exhibits general statistical continuity in its path toward a certain equilibrium, but within this *general* continuity there appear to be *detailed* discontinuities.

The use of equations for representing growth has been criticized because they do not give insight into the detailed growth mechanisms. Neither does the law of gravitation explain detailed mechanisms of gravitation; it only claims rational meaning for its constants. The equations we employed represent regularities, namely that the growth

⁴⁹ Lerner, I. M., *Science*, **89**, 16 (1939).

⁵⁰ Romanoff, A. L., *Science*, **70**, 484 (1929).

rate tends to be directly proportional to the number of reproducing cells or to the available "living space" and the equation constants have definite, rational, physical meaning. If the value of k in our equation is constant, it means, by definition, regardless of theory, that the percentage growth rate is constant during a given time interval. If the value of k changes, the percentage rate of growth changes. The use of this equation to describe data is intended to assist and to guide, not to replace experimental analysis, as has been mistakenly suggested. Experimental and mathematical analyses, like other action and thought, are mutually supplementary.

Fig. 16.61. Age changes in the ratios of size of girls to boys. At birth and at age 13 years girls are about 6 per cent heavier than boys; on approach to maturity the boys overreach the girls to the extent of about 20 per cent for weight and 8 per cent for height. (See Chapter 7 for endocrinological mechanisms.)

On the basis of physico-chemical considerations of the growth process, Robertson⁵¹ inferred that growth is an autocatalytic process and that the velocity of growth may be limited by a monomolecular autocatalytic chemical reaction, given by the equation

$$dW/dt = kW(A - W)$$

indicating that the velocity of growth is a function of both growth already made and growth yet to be made.

This equation represents a symmetrical curve, while growth curves are not usually symmetrical; that is, the inflection does not occur in the center of the curve (Figs. 16.57a and b). Attempts to rationalize this^{51, 52} lead to practical difficulties. For this reason we broke up the curve into its components and represented them by the equations $dW/dt = k_1W$ and $dW/dt = k_2(A - W)$, which proved successful in our hands as indicated by the many curves in this chapter.

⁵¹ Robertson, T. B., "Chemical basis of growth and senescence," Lippincott, 1923.

⁵² Crozier, W. J., *J. Gen. Physiol.*, 10, 53 (1926).

To overcome the difficulty of asymmetry in Robertson's equation, Pearl and Reed⁵³ converted it to a potential series function of time, t , given by the relation

$$\frac{dW/dt}{W(A - W)} = k_1t + k_2t^2 + k_3t^3 + \cdots + k_nt^n.$$

Pearl and Reed were concerned with the integrated form of this equation, namely

$$W = d + \frac{A}{1 + me^{k_1t + k_2t^2 + k_3t^3 + \cdots + k_nt^n}}$$

Fig. 16.62a. Measuring the height of withers at the highest point. The horizontal arm and vertical arm of the measuring device are equipped with built-in spirit levels to help keep the measuring rod in strictly vertical position.

They found it elastic enough to fit the growth curve of the rat, but only beginning with 10 days after birth, as shown in Fig. 16.58. It does not represent the curve from conception to 10 days following birth, the most important developmental stages in the life history. The numerical values of the constants, k , k_1 , $k_2 \cdots$ change with the number of constants employed. Hence, one cannot give definite, numerical meaning to the constant, and it is therefore, from our special viewpoint, irrational.

Another well-known growth equation is that of Gompertz⁵⁴

$$W = Ae^{-e^{-t}}$$

⁵³ Pearl and Reed⁴⁶ and many other papers.

⁵⁴ Gompertz, S., *Phil. Trans. Roy. Soc.*, p. 522 (1825).

in which W is the size of the organism or population at time t , A is maximum size, and e is the base of natural logarithms. It is also written as $W = Ae^{ekt}$.

Its many constants make it a potential series, and it is therefore meaningless from our viewpoint. It states that for a given growth cycle the log-logs of the percentage of growth increase directly with time. Courtis⁵⁵ employs this equation widely for growth.

Many other equations have been proposed which we have not discussed, partly because they fail to meet the criterion of definiteness and rationality of meaning of the constants (Sect. 10.10).

Fig. 16.62b. Measuring heart girth.

In summary, it does not appear possible to represent the entire growth curve by one equation, not even by the very plastic potential series equations. In other words, growth curves appear to have metamorphosis-like discontinuities^{56, 57}.

⁵⁵ Courtis, S. A., *Growth*, 1, 155 (1937).

⁵⁶ Davenport, C. B., "Human metamorphosis," *Am. J. Physical Anthropol.*, 9, 205 (1926), and *J. Gen. Physiol.*, 10, 205 (1926).

⁵⁷ Knibbs, J. H., *J. Am. Stat. Assn.*, 21, 381 (1926), and 22, 49 (1927), reported that the time curve of human populations show breaks. For other critical discussions of growth equations, see Yule, G. V., *J. Roy. Stat. Soc.*, 88, 1 (1925); Crozier, W. J., *J. Gen. Physiol.*, 10, 53 (1926); Gray, J., *Brit. J. Exp. Biol.*, 6, 248 (1928-29); Wilson, E. B., and Puffer, R. R., *Am. Ac. Arts and Sci.*, 68, 285 (1933).

Wetzel⁸⁸ published an elaborate, perhaps rational, analysis of growth as a "mode of motion." Unfortunately, the writer is not able to follow his detailed analyses.

16.10: Summary. Growth is self-multiplication of reproducing units, either of individuals in a population or of cells in a multicellular organism. Growth curves of populations and of multicellular organisms are remarkably similar.

Fig. 16.62c. Measuring the distance from a point of shoulders to ischium.

Broadly speaking, the growth curve is molded by two factors: (1) an expansive drive tending toward expansion of self or kind, to multiply indefinitely, and (2) an environmental pressure which keeps the expansive urge under control.

Early in the history of the individual or population when growth is unrestricted by the environment, the *percentage* growth rate tends to remain constant as represented by the rate equation, $dW/dt = kW$, or by the cumulative equation, $W = Ae^{kt}$. The proportionality constant, k , is the relative, or when multiplied by 100, the *percentage* growth rate of the population or individual under the given conditions, computed on the differential or instantaneous-rate basis.

The *instantaneous* percentage rate, $100k$, of growth in the earliest, unrestricted, phase of growth is in the chick during the first 5 days about 100 per

⁸⁸ Wetzel, N. C., *Growth*, 1, 6 (1937), and many other papers.

cent *per day* (doubled in 17 hours), and probably also in the rabbit, mouse, rat, monkey, and guinea pig. The instantaneous rate of growth of a pumpkin under field conditions was 40 per cent *per week* (doubled in weight in 1.7 weeks); of a wheat plant, 74 per cent *per week* (doubled in 0.94 week); of a barley plant, 60 per cent *per week* (doubled in weight in 1.2 weeks).

During the unrestricted phase of *population growth* the instantaneous percentage growth rate was 185 per cent per hour (doubling in 0.37 hour) for *B. coli* at 37° C; 47 per cent per hour (doubling in 1.5 hours) for lactic-acid ac-

Fig. 16.62d. Measuring the width of hips.

cumulation in milk by *B. l. a.* at 25° C: 2.9 per cent per year (doubled in 24 years) for the growth of the human population in the United States during 1660–1860, and so on.

After the individual or the population attains a certain size, the environmental limitation retards the intrinsic growth rate and the slope of the growth curve is reversed from increasing to decreasing. This slope reversal coincides with puberty in animals, flowering in plants, and with a tendency to overcrowding in populations. While there is great diversity in the *detailed* mechanisms actuating the reversal in the shape of the curve, the *general* feature—shape of the curve—is the same whether the growth is populations of men or flies trapped in an isolated space, or cells trapped in the body of a

multicellular organism. Environmental limitations finally bring the growth process to a standstill, although the maintenance aspect of growth continues for some time in individuals and may continue indefinitely in populations. Cessation of growth in *individual* organisms always leads to senescence and death (Ch. 18). A similar fate of senescence and death overtakes *some* populations in some environments, such as of yeast in fermenting juice or lactic-acid organisms in milk. Populations which are members of broader cycles, such as mice or men, are apparently able, in the absence of some catastrophe, to reproduce and thus "keep the population young" indefinitely (at least in theory).

The rate of growth following the permanent reversal or major inflection in the slope of the age curve is no longer proportional to the existing size, W , of the population or organism, but to the available "living space", reflected by the growth yet to be made, represented symbolically by $A - W$, in which A is the mature or maximum value of the population or of the individual. The instantaneous growth rate during this period is consequently represented by the rate equation $dW/dt = k(A - W)$; or the total population or organism size at age t is given by the integral equation $W = A - Be^{kt}$. The proportionality constant k is the relative or, when multiplied by 100, percentage growth rate in respect to growth yet to be made to reach the mature size A , as contrasted to the k for the early, unrestricted, phase of growth which represents the relative growth rate with respect to growth already made, to the size, W , of the reproducing population or organism.

The numerical value of k for the phase of growth following the major inflection in the curve tends to vary with the mature size of the population or organism. It is 0.04 to 0.05 (that is, 4 to 5 per cent) *per month* in cattle (80 to 100 months required to reach 98 per cent mature weight); 0.35 to 0.70 *per month* in rats (6 to 12 months required to reach 98 per cent mature weight); 0.62 to 0.80 *per month* in mice (5 to 7 months to reach 98 per cent mature weight); 0.80 to 1.6 *per month* in pigeons (3 to 7 months to reach 98 per cent mature weight); 0.025 *per year* in humans (18 to 25 years to reach 98 per cent mature weight); 0.47 *per day* in a yeast population; 0.08 *per day* in an oat plant; 0.26 *per day* in a squash plant, and so on (Table 16.1).

It is evident that the mass-action principle may be applied to both early (self-accelerating) and late (self-inhibiting) phases of growth. In early growth the rate of growth tends to be proportional to the growth already made, W , and in late growth to the growth yet to be made ($A - W$).

The principle of mass action is applicable to many non-biologic types of growth, such as to the rate of increase of an inorganic product in a chemical reaction. Indeed, the principle of mass action was originally formulated by Berthollet (1799) and substantiated experimentally by Wilhelmy (1850) for chemical reactions *in vitro*, and, independently, by economists for economic processes in the form of the law of diminishing returns (Ch. 5). The expansion

of many economic enterprises tends to follow a course similar to growth with early, apparently unlimited (self-accelerating) prosperity, gradually shifting into an era of diminishing returns. The mechanisms in these various processes are, of course, very different in detail but very similar in general plan (Ch. 5). The inherent limitation of the universe controls any type of indefinite expansion.

The equations of the two segments of the time curve of growth, as for chemical reactions, may be combined into one equation, $dW/dt = kW(A - W)$, which represents the rate of the autocatalytic monomolecular reaction of the physical chemist, widely used with slight modifications by Robertson and Wolfgang Ostwald, which attracted much attention and exerted great influence on the growth literature. Many modifications of this equation have been used by adding constants, thus turning it into a potential series, plastic but less meaningful. No equation has been found to represent *the whole* of the growth cycle of animals, although the Robertson-Ostwald and the Verhulst-Pearl-Reed equations were meant to be such. The actual growth curve shows breaks, illustrated most dramatically by metamorphosis in cold-blooded animals (from tadpole to frog, from larval to fly stage), birth, hatching and puberty in warm-blood animals, and change from aquatic to terrestrial modes of respiration in birds (chicks during the 18th day of incubation). There appear to be similar irregularities in the growth of populations. For this reason, we prefer to break up the age curve, as far as possible, into its significant constituent segments and employ separate equations with rational, clearly defined, constants to represent each segment.

Discussions are presented on genetic growth constants, together with numerical values of mature size of different species of animals, and times required to reach different fractions of the mature weight; on the relation between average and individual growth curves; and on some common factors influencing growth rates.

These equations are used in Chapter 19 for evaluating growth equivalence.

16.11: Appendix. This section contains several sets of numerical growth data, some genetic growth constants, and several charts which could not be included in the text.

Growth of dairy cattle. These data are based on Missouri Station Bulletin 336, 1934, by Ragsdale, *et al.*, and are also presented graphically in terms of weight and height as functions of age, and also in terms of gains per month (Figs. 16.59a to f).

We published a great deal of data, with their sources, on growth of various laboratory and farm animals in Missouri Res. Bul. 96. It would take too much space to reproduce them in this book, but most of them are represented in graphic form in the text of this chapter. Moreover, readers not familiar with the various classes of laboratory and farm animals will not appreciate the significance of the numerical data. However, everyone appreciates the

significance of weights and heights of children; so the most recent data ^{59, 60} on growth of children are here presented, both for the average of all children measured (average of about 700 for each age) and for "early maturing" and "late maturing" (those having the "prepubertural acceleration" early and late).

⁵⁹ Shuttleworth, F. K., "The physical and mental growth of girls and boys age six to nineteen in relation to age at maximum growth," Monographs of the Society for Research in Child Development, Vol. 4, no. 3, Serial 22, 1939, National Research Council, Washington, D. C. For ages 1, 2, 3, 4, and 5 years, the data are after R. M. Woodbury, U.S.D. Labor, Children's Bureau, Pub. 87, 1921.

⁶⁰ For the compilation of most available data on growth of children, see Baldwin, B. T., "The physical growth of children from birth to maturity," *Univ. Iowa Studies in Child Welfare*, 1, no. 1 (1921).

¹ The percentage of monthly persistency of growth, 100P, may be obtained by subtracting the percentage decline, 100k, from 100; i.e., 100 P = 100 - 100 k.

² By age is meant, in all cases, are as counted from conception. The following ages of the animals at birth are given should the reader desire to convert the conceptional ages to birth ages: Cattle 9.4 mos., horse 11 mos., swine 4.0 mos., sheep 5.0 mos.; rabbit 1.0 mos.; fowl 0.7 mos. (21 days); guinea pig 2.2 mos. (67 days); mouse 0.66 mos. (20 days); pigeon 0.6 mos. (18 days); man 0.79 yrs. (9.5 mos.).

Chapter 17

Linear Growth, Form, and Function

Geometric laws determine physiologic processes. *G. Teissier*

The more the organism changes the more it remains the same. *A. H. Hersh*

Remember that "formative substances", hormones, vitamins, genes, and similar controlling agencies, are merely mechanisms of a more deeply seated control which knits the mass of living stuff into an organism. We seek the architect, not the maker of builder's supplies. *E. W. Sinnott*

17.1: Introduction and definitions. The basic problem of organization is how genetically identical cells give rise to histologically diverse ones, and how growth occurs at different rates in different directions resulting in differences in size, form, and function. Many factors have been investigated and found to be influential: genes, hormones, auxins, organizers, evocators, competency, morphogenetic fields, organic gradients, electrical fields, electric currents, light, gravity, heat, mechanical pressure, enzymes, sulfhydryl, minerals, vitamins, proteins, amino and nucleic acids, fats, carbohydrates, and so on. There is an enormous literature¹ on these influential factors and mechanisms, some of which are discussed elsewhere in this book. The present chapter is not concerned with these factors, but, like the preceding chapter, with the numerical relationships of part to whole during increase in size, and with very general explanations concerning the interrelationships between size, form, and function². These problems have very important relations to agriculture and nutrition, as illustrated by the preoccupation of animal husbandmen with livestock judging (see below).

Let us then discuss the general problem of change in form with increasing age.

Fig. 17.1a (caption next page)

Fig. 17.1b. Weight, chest girth, and height at withers of full-fed and under-fed steers plotted against age on arithlog paper. Note the *relative* rate of increase of these three indices of size, and the influence of the plane of nutrition on them.

Fig. 17.1a. Influence of nutrition and selection on change in bodily proportions. The charts are from reprints sent to the writer by John Hammond, Cambridge University. Photographs of all animals were reduced to the same height at shoulder so as to compare change in proportions as distinct from change in size. Note that the body proportions of the pork type at 100 lb are the same as of the bacon type at 200 lb. Note the difference in proportions in under-fed and well-fed. Note the various methods of approaching to body weight 200 lb, and photograph of animals raised up to 200-lb by two different methods ("high-low" and "low-high") with differences in "type" thereafter. Differences in food supply at different ages accelerates selectively, the early or late developing tissues thus changing bodily proportions. References to Hammond, McMeekan and associates are given in the text.⁹ For the pig charts, see especially C. P. McMeekan and J. Hammond, *Empire J. Exp. Agr.*, **8**, 8 (1940), and *J. Ministry of Agric.*, **46**, 238 (1939); and Hammond, J., *J. Roy. Agr. Soc. England*, **93**, 1 (1933). For the sheep, Hammond, *The Farmer and Stock Breeder Agricultural Gazette* (England), Dec. 10, 1928. Note that in the improved breed of sheep (left) the changes in bodily proportions are pushed to a further "stage" than in the wild type (right). This is true of other domestic animals selected for "further stages" of development at earlier ages. What was accomplished by selection and selective feeding, may perhaps be accomplished by other methods (hormone administration, etc.).

In geometrically similar bodies³, such as small and large spheres, surface, S , is proportional to the square of linear size, L , and volume or weight, V or W , is proportional to the cube of linear size, as shown by equations (17.1)⁴:

Fig. 17.1c. Marine animals (small and large fish) were apparently not under the compulsion of gravity (and other factors) to change in external body form; land animals apparently were under such compulsions as indicated, for example, by the relatively larger heads in the new-born land species. New-born cattle, sheep, goats, horses, and related species have long legs and short, shallow bodies. On maturing, especially in the improved meat breeds, the buttocks and loins grow at a faster rate than the head and legs. The greater the "improvement" the more rapid the relative increase in these "meat parts." Sources of data: Dairy cattle, original (photographs reduced to the same height at withers). Rabbit, from John Hammond, Yearbook National Rabbit Council, England, 1931 (photographs reduced to the same cranium size to show increase in body in contrast to that of the head). Fish, from Hecht, and man, from Strantz, both as cited by C. M. Jackson in the book "Growth," by W. J. Robbins, S. Brody, C. M. Jackson, A. G. Hogan and C. W. Green, Yale Press (1928). For man, see also Edith Boyd: "Outline of Physical Growth and Development," Burgess, Minneapolis, Minn. (1941).

³A large body is *geometrically similar* to a small body if all the linear dimensions of the large body have the same proportions to one another as those of the small body. Thus, for a large cylinder which has double the diameter of a small one to be geometrically similar to the small, it is necessary that the length of the large cylinder also be double that of the small cylinder.

⁴The growth of a spherical organism:

Diameter	1	2	3	4
Surface Area	1	4	9	16
Volume (weight)	1	8	27	64

Spherical organisms cannot attain a large size because the surface cannot keep up with the volume.

$$S \propto L^2 \text{ and } W \propto L^3 \quad (17.1)$$

Since from the above relation

$$L \propto W^{\frac{1}{3}} \text{ and } S \propto L^2,$$

Fig. 17.1d. Age curves of growth in weight and in several skeletal structures plotted in terms of percentage of maximum size. All these age curves follow the same equation, $Y = A - Be^{-kt}$ (in which Y is size at age t and A is maximum size), but the rate, k , of approach to maturity, A , is different for each of these structures. These differences in the rate of approach to maturity lead to change in form with increasing age. While each structure approaches maturity at a rate characteristic of the given structure, different from the rates of growth of other structures, yet the ratio between the percentage change in weight and linear size is approximately constant, b , as indicated by the equation $Y = aX^b$, in which Y is weight, or size of any structure and X is the size of any other structure. Dairy Cattle.

therefore,

$$S \propto (W^{\frac{1}{3}})^2 = aW^{\frac{2}{3}} \quad (17.2)$$

Equation 17.1 shows that during the growth of a body its surface size tends to increase more rapidly than its linear size, and that its volume, or weight

size, tends to increase more rapidly than its surface size. Equation (17.2) shows that the surfaces of the body tend to increase, by *geometric necessity*, with the $\frac{2}{3}$ power of weight, $W^{\frac{2}{3}}$. However, necessity for physiologic homeostasis (Ch. 10) tends to modify the geometric relations in growing

Fig. 17.1e. Differences in the rate, k , of approach to mature height and weight in American boys. Both weight and height at given ages are expressed as percentages of the mature values. Note that this chart may be used for predicting future weights or heights. At 9 years, for example, a boy attains 38 per cent and at 12 years 50 per cent of the mature weight. Therefore, if a boy weighs 23 kg at 9 years, his mature weight will be $23 \times \frac{100}{38} = 60.5$ kg; at 12 years he will weigh $23 \times \frac{50}{50} = 30.3$ kg or $60.5/2 = 30.3$ kg, and so on.

animals. Large and small animals are not similar geometrically but rather tend to be physiologically, *i.e.*, homeostatically, similar: The organism changes geometrically so as to remain the same physiologically. The age curves of growth in different dimensions or in different components tend to be so adjusted as to give the animal mechanical stability and metabolic or physico-chemical homeostasis. The general discussion may be illustrated by a few concrete examples.

Fig. 17.2a. Relative-growth in terms of percentage of one organ, Y , to another or to body weight, X , plotted against age on arithmetic paper. Note the break in the liver curve.

The surfaces are involved in all metabolic processes, including digestion, assimilation, respiration, excretion, secretion, including secretion of hormones. Heat dissipation, likewise, occurs by way of the surface portals (Chs. 11, 13). The metabolic processes, therefore, tend to become ever more cramped with

increasing size of the body; they tend to decline per unit weight of body; indeed, they tend to be proportional to the square of the linear size, that is to surface area, $W^{\frac{2}{3}}$. This is not a uniquely biologic phenomenon. The power of an engine likewise tends to vary with the square of its linear size, with its surface area, $W^{\frac{2}{3}}$, rather than with its weight, $W^{1.0}$. This is a basic geometric interrelation as indicated in footnotes 3 and 4.

Then, too, while the weight of a body increases with the cube of its linear size, the strength of its supporting structures, such as of the legs, tends to

Fig. 17.2b. Ratio of organ weight to body weight plotted against body weight on arithmetic paper. The scales have to be frequently changed in order to crowd in all data. Arithmetically divided paper does not permit plotting significantly wide ranges of data.

increase with the cross-section areas of these structures, that is, with $W^{\frac{2}{3}}$. Here mechanical strength and stability tend to decline with increasing size.

In the course of time several devices were evolved to compensate for the decline in the ratios of surface to weight and strength to weight. The decline in the surface-to-weight ratio is compensated, in part, as illustrated by the kidney and lung structures, by various types of folding, packing, invagination, convolution, coiling, and so on. The decline in the ratio of strength

to weight is compensated in part by relatively larger increases in the size of the supporting structures than in the non-supporting visceral organs. Thus it comes about that per unit total body weight larger animals have larger muscles and bones than internal organs; or what is the same, the larger the animal the smaller the ratio of visceral-organ weight to body weight.

Fig. 17.3. Organ weight (lung, kidney, brain, liver) plotted against body weight for prenatal growth. The numerical values of the exponents or slopes in the equation $Y = aX^b$ are given for several intervals. Note their changes.

The *functional* changes resulting from this change in *form* are far-reaching. Since the levels of all metabolic processes are dependent on, or activated by, the visceral organs, and since the ratio $\frac{\text{visceral-organ weight}}{\text{body weight}}$ declines with

increasing body size, the ratio $\frac{\text{functional level}}{\text{body weight}}$ must also, and does, decline with increasing body size.

Fig. 17.4. Organ weight as function of body weight plotted on a log-log grid. For sources of data see Edith Boyd: "Outline of physical growth and development" (Burgess, Minneapolis, Minn., 1941). See also Vierordt, H., "Anatomische Daten und Tabellen" and "Tabulae Biologicae."

As a result, most metabolic processes increase not directly with simple body weight, $W^{1.0}$, but with a fractional power of body weight, i.e., the 0.6 to 0.8 power of body weight, or approximately, $W^{0.7}$. This means that increasing body weight by 1 per cent increases the metabolic rate not by 1 per cent but only by 0.7 per cent; the metabolic process increases about 70 per cent as rapidly as body weight. Thus (Ch. 13) the basal energy metabolism of a 100-kg animal is 2070 Cal/day; of a 200-kg animal it is not

4140 Cal/day (twice 2070) but only 3450 Cal/day. While the body increased 100 per cent, from 100 to 200 kg, the metabolism increased $\frac{3450 - 2070}{2070} = 68$ per cent. Likewise (Chs. 21, 22) we know a 120-lb goat that produced 14 lbs of milk a day but it is probably impossible for a 1200-lb cow to produce 140 lbs of milk a day. A 1200-lb cow may, perhaps, produce 7-fold that of a 120-lb goat, namely 100 lbs of milk a day, but certainly not 10-fold.

This whole discussion adds up to this conclusion: change in size is associated with change in *form* and also with change in *function*. Indeed, func-

Fig. 17.5a. Supplementing the "atypical" curves (gonads, adrenals) in Fig. 17.4 for man with charts for adrenal weights of animals of different species (Brody and Kibler).

tion and form are two aspects of the same thing. To be sure, we cannot predict or judge with precision the function from the form, but this is because of our observational limitations; the external features constitute an insignificant aspect of the structure and organization of the body as a whole.

Summarizing, the necessity for changing the form with increasing size in land animals lies in these geometric facts: (1) weight, which tends to crush the land animal's limbs and which has to be moved by the muscles, varies with the cube of linear size; (2) tensile strength of the muscles and bones

which move and support the animal varies with the square of the linear size (cross-section area) of the muscles or bones; (3) surfaces, through which diffusion, nutrition and excretion take place, vary with the square of linear size. Only animals which have evolved a form in harmony with physical or geometric laws on one hand and physiologic needs on the other hand have survived. This situation prompted Lambert and Teissier⁵ to remark that while

Fig. 17.5b. Adrenal weights of growing rabbits (Kibler, Bergman, and Turner).

physiologists search for a physico-chemical explanation of living phenomena, many physiological laws may be anticipated deductively from geometric and physical interrelations. In fact, about 200 years ago, Galileo, with the aid of his *theory of similitude*, demonstrated that a man cannot build a house, nor nature construct an animal beyond a certain size without changing the form or materials; in other words, large and small organisms cannot remain

⁵Lambert, R., and Teissier, G., "Theorie de la similitude biologique," *Ann. Physiol. et physico-chim. biol.*, #2, p. 22 (1927).

geometrically similar and survive. Aquatic animals are not forced to change much in form with increasing weight because their weight is counterpoised by the displaced water. Changes in form during growth are illustrated in Fig. 17.1a and c.

Differences in body build within the species and breed are, of course, due to special genetic constitutions and to nutritional conditions not explained by the above general principles. Thus persons are classified⁶ as fat or pyknic, muscular or athletic, and thin or asthenic. The fat type is characterized by a long digestive tract (25-30 feet of small intestine), whereas the thin type has a short tract (10 to 15 feet of small intestine). There are similar type differences in farm animals, as beef and dairy cattle⁷, "dairy" temperament, and so on, and the judging of livestock is mostly judging for type.

Fig. 17.5c. Thyroid weights of the same growing rabbits as in 17.5b (Kibler, Bergman, and Turner).

Food supply (qualitative, quantitative, and age distribution) exerts a profound influence not only on growth rate and total body weight but also on bodily proportions, "type", and productive capacity. Research on the influence of food supply on type has been pioneered at the Missouri Station⁸ and is being pushed vigorously not only in many stations in this country, too many to cite, but especially by the Cambridge (John

Hammond) School⁹ (Fig. 17.1c). McCay is investigating this problem especially from the viewpoint of resistance to disease and longevity (Sect. 18.2.4).

One author¹⁰ based his designations of human types as "herbivorous" (fat) and "carnivorous" (thin) on differences in length of the small intestines. Another author⁶ designated the fat type as endomorphic or viscerotonic because in this type the digestive viscera, which are derived from the endodermal layer, predominate.

The fact that some individuals have longer digestive tracts than others should be helpful in dietary adaptation to the respective constitution. Spinach, cabbage and bran may do very well for the "herbivorous" but not the "carnivorous" type, who may need more concentrated victuals.

While a wise physician may recognize a patient's ailment by his "knock on the door", the appearance of his hands¹¹ or tongue, medical statisticians¹² have computed mathematically the degree of correlation of various ailments to body type, with the result that the fat appear to be inclined to gall bladder and circulatory ailments and to cycloid (manic-depressive) mental disorders; the thin more predisposed to tuberculosis, stomach ulcer, allergies, and to chizoid (schizophrenic) mental disorders. Because of the greater surface area per unit weight in the thin, with corresponding greater exposure of

Fig. 17.5e. Kidney weight of growing cats (Brody, plotted from unpublished data by Hall) showing an apparent "break" paralleling the adrenal "break." (Cf. p. 625.)

nerve endings to the surroundings, the thin is likely to be more sensitive, irritable, high strung and introvert than the fat, who is likely to be easy going, cheerful and extrovert.

The endocrine background is likely to differ in the various types (Ch. 7). It is generally known that the basal metabolism tends to be higher in the muscular and the tall-thin, than in the fat, which may reflect greater thyroid activity in the muscular and tall-thin

than in the fat. On the other hand, the fat tend to be hypopituitary and hypogonadal (Frohlich syndrome) and the muscular tend to be hyperpituitary (acromegaly).

17.2: Notes on dimensional analysis.¹² The method of dimensional analysis is comparable in simplicity, power, and generality to that of thermodynamics. The method of dimensional analysis, being geometric in nature, is not concerned with detailed mechanisms, but, like certain aspects of thermodynamics, it expresses statistical results of certain interactions. Thus power functions such as the one discussed in Chapter 13,

Fig. 17.6. The relation of organ weights to body weight in mature cattle. The curves represent the equation $Y = aX^b$ fitted by the method of least squares to data kindly furnished by W. W. Swett, Bureau of Dairy Husbandry, U. S. Dept. of Agriculture. For description of animals see Swett, W. W., and Graves, R. R., *J. Agr. Res.*, 58, 199 (1939). The numerical values at the beginning and end of curves represent the organ weight in pounds for 800 and 1600 pound cattle.

concerned with the relation between metabolism and body weight, or such as will be discussed in a later section of this chapter, may be derived analytically and *independently* of detailed physiologic or biologic considerations. Thus energy-producing (as

¹²See D'A. W. Thompson²; Tolman, R. C., "The principle of similitude and the principle of dimensional homogeneity," *Physical Rev.*, 6, 219 (1915); 9, 237 (1917). Étude de biometrie théorique," *Id.* 4, 1 (1928).

“basal metabolism”) properties vary with the square of the linear dimensions, regardless of whether the body is an animal or a steam engine, while the weight of the body, animal or engine varies with the cube of the linear dimensions; hence from dimensional analysis, the heat production or available long-range energy will tend to vary with the $\frac{2}{3}$ power of the weight of the animal or engine.

Fig. 17.7. Summary of the curves representing the relation of organ weight to body weight of mature mammals (heavy lines) and birds (light broken lines) of different species. The numerical values of the slopes (b in the equation $Y = aX^b$) and of the standard error, S_b , of the slopes, b , are given for each curve. The low values of S_b indicate a high degree of stability for these slopes, especially for the mammals.

This derivation is independent of the fact that the body is living. The “surface law”, relating basal metabolism to surface area, on the other hand, is derived not from general physical or geometric laws, but from the biologic consideration that in the course of evolution only those animals survive whose rate of heat production balances their rate of heat dissipation, which is proportional to surface area (square of linear

Fig. 17.8a. The relation of brain weight to body weight plotted on a log-log grid. The given data points are for *mature mammals* only. The heavy continuous line represents the equation $Y = aX^b$ fitted, by the methods of least squares, to *mature mammals* of different species. The broken curve similarly represents *mature birds*; the other curves (GR) represent the indicated animals in various stages of growth. The five broken lines represent the standard error of estimate, S_r , including between them $\frac{1}{2}$ of the data points. The letter rho represents the Index of correlation, corresponding to the coefficient of correlation for linear equations. All charts follow the same system.

dimensions). Dimensional analyses also lead to the conclusion that while a linear equation relating metabolism to body weight may be practically as satisfactory, it is less rational than a power (logarithmic or parabolic) equation.

According to dimensional analysis, metabolism varies with the $\frac{2}{3}$ power of weight in geometrically similar figures. Actually metabolism does not vary with the $\frac{2}{3}$ power of weight, because the large animal is not geometrically similar to the small, due to change in form and substance during growth, as might be expected, again, from dimensional analysis and the principle of similitude. The method of dimensional analysis thus predicts that metabolism should vary with a fractional power of weight, close to the $\frac{2}{3}$ power of weight, but not exactly with the $\frac{2}{3}$ power of weight. It has been suggested that the weights of certain visceral organs should, like surface area, vary with the square

Fig. 17.8b. Blood weight, unlike brain weight, shows a virtually linear relation to body weight and slight species differences. The heart (Fig. 17.10) also tends to vary linearly.

of the linear dimensions¹⁴ and that excitation¹⁵ should also vary with area (of the excitable elements).

The method of dimensional analysis is said to have been formulated by Fourier and also by Galileo. The method (1) postulates that many quantities (see the following

¹⁴Brandt, A., "Das Hirngewicht und die Zahl der peripherischen Nervenfasern in ihrer Beziehung zur Körpergrösse," *Biol. cent.* 18, 475 (1898). Du Bois, E. "Sur le rapport du poids de l'encephale avec la grandeur du corps chez les Mammiferes," *Bull. Soc. Anthropol.*, 8, 337 (1897).

¹⁵Cf. Crozier, W. J., and Holway, A. H., "Theory and measurement of visual mechanisms," *J. Gen. Physiol.*, 23, 101 (1939).

table) are derivable from a few fundamental quantities or dimensions, and (2) specifies that the dimensions on the two sides of a physical equation must be homogeneous and balanced. Skill in the use of dimensional analysis involves familiarity with the funda-

Fig. 17.9a. Pituitary weight of different species (Brody and Kibler, Mo. Agr. Exp. Sta. Res. Bull. 328), and of rabbits (Kibler, Bergman, and Turner).

mental and derived quantities or dimensions and definitions, and facility in algebraic technique.

There are several—there were formerly three but they were increased by Tolman to

Fig. 17.9b. Pituitary weight of different species (Brody and Kibler, Mo. Agr. Exp. Sta. Res. Bull. 328), and of growing rats (insert).

Fig. 17.9c. Pituitary weight of guinea pigs [Mixner, Bergman, and Turner, *Endocrinology*, 31, 59 (1942)].

five—fundamental dimension or quantities, namely (1) length, l , fundamental for spatial quantities; (2) time, t , for temporal quantities; (3) mass, m , for mechanical quantities; (4) electric charge, e , for electrical quantities; (5) entropy, or degree of “run-downness”, S , for thermodynamic quantities.

Other kinds of quantity may be derived in terms of these five fundamentals. Thus it is customary to regard a quantity of velocity, v , as a quantity of length, l , divided by quantity of time, t ; a quantity of volume, v , as the product of three quantities of length; a quantity of density, d , as a quantity of mass, m , divided by a quantity of volume, and so on.

Fig. 17.10a. Heart weight vs. body weight during prenatal growth (insert upper left) and in mature animals of different species. Note that the “athletic” land animals have relatively larger hearts than the non-athletic and marine animals.

Velocity is said to have the dimensional formula of length divided by time, symbolized by the formula, $l t^{-1}$ (or l/t); likewise, momentum, which is quantity of mass, m , multiplied by a quantity of velocity, $l t^{-1}$, is said to have the dimensional formula $ml t^{-1}$. The dimensional formula is a shorthand statement of the definition of that kind of quantity in terms of quantity chosen as fundamental, and hence is also a partial statement of the physical nature of the quantity in question.

The following table illustrates the above discussion.

SPATIAL OR GEOMETRIC QUANTITIES

	Symbol	Dimension
Length.....	l	l
Area.....	A	l^2
Volume.....	V	l^3

TEMPORAL OR KINEMATIC QUANTITIES

Time.....	t	t
Velocity, linear speed.....	v	lt^{-1}
Acceleration.....	a	lt^{-2}
Frequency, revolutions per unit time.....		t^{-1}

Fig. 17.10b. See legend for Fig. 17.10a.

There are, similarly, mechanical, thermodynamic, and electrical quantities.

The following simple dimensionally homogeneous equations were previously discussed (Ch. 13) in connection with the area problem.

The equation

$$A = V^{1/2}l$$

(Note: A = surface area, V = volume, l = linear size)

is dimensionally

$$l^3 = l^{3/2} l = l^3$$

The equation

$$A = V^{1/2} l^{1/2}$$

is dimensionally

$$l^3 = l^{2 \times 1/2} l^{1/2} = l^3$$

The equation

$$A = V^{.426} l^{.725}$$

is dimensionally

$$l^3 = l^{3/2 \times .426} l^{.725} = l^{1.276} l^{.725} = l^3$$

Fig. 17.11. Linear measurements taken of dairy cattle, described in Table 17.7, page 650, and referred to in Figs. 17.12a and b. For measuring methods see Figs. 16.62a to d (pp. 560-563).

From the above and other dimension equivalents, it may be shown that in bodies geometrically, chemically, physically, and environmentally similar, heat production should vary with the square of linear size; likewise, in similar animals under similar conditions, heat production should vary inversely with the squares of the pulse rate or respiration rate (heart rate and respiration rate, being frequencies, have the dimension of $1/t$ or t^{-1}) or directly in proportion to the amount of blood supply (which is the product of pulse rate and volume of blood, having the dimension of l^3); or what is the same, the heat production *per unit weight* should vary inversely with the cube root of weight ($Q/W = aW^{-1/3}$, which is the same as $Q = aW^{2/3}$) or directly with the pulse rate or respiration rate (Sect. 24.5.4).

17.3: Equations relating part to whole. The method of dimensional analysis is strictly applicable only to bodies which are similar in space and time, such as small and large spheres. Since small and large animals—infants and adults, for example—are not similar in space and time, this

Fig. 17.12a. Age course of linearly measured complexes (Fig. 17.11). The continuous curves represent the equation $Y = A - Be^{-kt}$ fitted to the data. For the value of the constants see Table 17.7.

method is useful for rough approximations only. An empirical—less logical—approach is more inviting at this time.

Common-sense considerations and experience, especially in chemistry, physics, and engineering, and even in economics, indicate that the *percentage change* in one variable tends to vary directly with the *percentage change* in a

related variable. As percentage change is the same as logarithmic change, one may say that the logarithmic change in one variable tends to vary directly with the logarithmic change in a related variable. A logarithmic equation has the same meaning as a parabola, a hyperbola, or a power equation, though it has a different form. To illustrate, it was shown (introductory section to this chapter, and Chapter 13) that surface area, S , varies with the $\frac{2}{3}$ power of volume or weight

Fig. 17.12b. See legend for Fig. 17.12a.

$$S = aW^{\frac{2}{3}}$$
 (1)

which is the power-equation or parabola form; in the straight-line logarithmic form it is

$$\log S = \log a + \frac{2}{3} \log W$$
 (2)

Equations (1) and (2) represent the same thing in different forms. Usually equations (1) and (2) are written

$$Y = aX^b$$
 (17.3)

and in terms of logarithms, which gives a linear form, it is

$$\log Y = \log a + b \log X \quad (17.4)$$

similar to the familiar linear equation

$$Y = a + bX$$

The exponent, b , which has the value $\frac{2}{3}$ or 0.67 for the area-weight relation, is the ratio of the percentage change in Y to the corresponding percentage change in X ; b is the slope of $\log Y$ plotted against $\log X$. For the area-weight relation, the percentage increase in surface area is $\frac{2}{3}$ that of the percentage increase in weight.

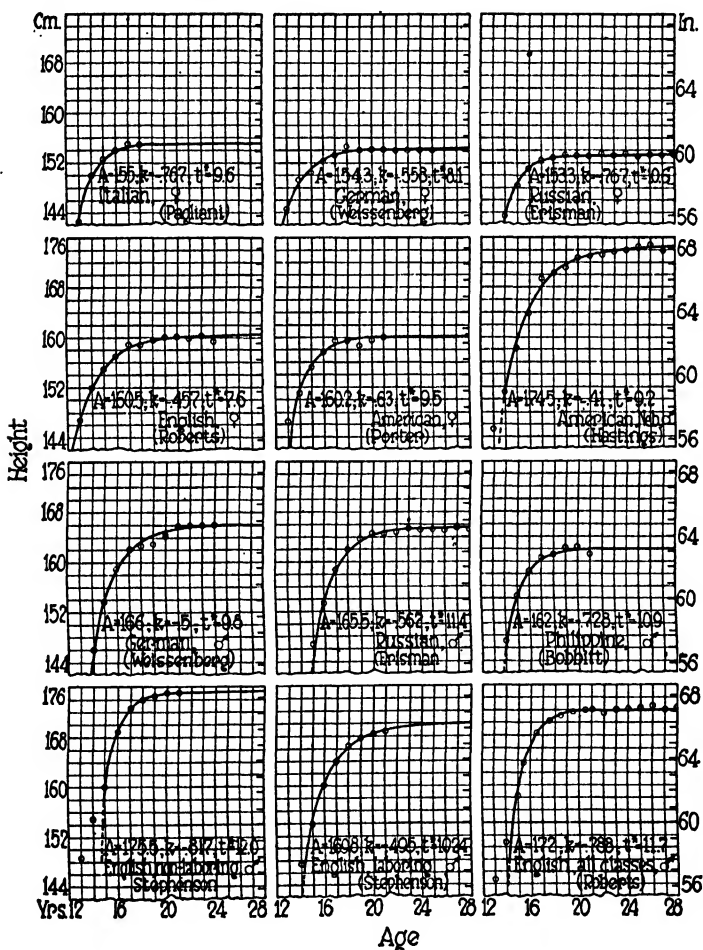

Fig. 17.13. Postpubertal growth in height of man. Note that the average mature height ranges from less than five to nearly six feet; yet all curves follow the course represented by the equation $Y = A - Be^{-kt}$. (The values of k and t^* are with respect to age in years for humans as contrasted to months for cattle.)

Likewise (Ch. 13) the basal metabolism, Y , varies with weight, X ,

$$Y = aX^{0.73}$$

or

$$\log Y = \log a + 0.73 \log X$$

Fig. 17.14a. Prepubertal growth in cattle proceeds at a constant *percentage* rate for weight (broken curve), and at a constant *time* rate for linear growth (smooth curves).

meaning that the percentage increase in metabolism, Y , is 0.73 time the percentage increase in body weight, X ; or increasing body weight, X , 1 per cent increases metabolism, Y , 0.73 per cent.

The method of fitting this equation to data is elementary and uninteresting, and has been described in detail in Chapter 13. The historic aspect is, on the contrary, interest-

ing and entertaining. About half a century ago, Snell¹⁶, DuBois¹⁷, and Lapicque¹⁸ wondered how brain size of different species should be compared in such a way as to demonstrate clearly that man's brain is proportionately larger than the brain of other species. They had no doubt that man's brain is relatively larger, although numerical comparisons gave ambiguous results. Thus comparison of absolute size (pounds, grams)

Fig. 17.14b. Postpubertal weight and linear growth in man decline exponentially ($Y = A - Be^{-kt}$); prepubertal weight growth in man increases exponentially ($Y = Ae^{kt}$) and linear growth, linearly ($Y = aX + b$). (Data from S. Weissenberg, "Das Wachstum des Menschen nach Alter, Geschlecht und Rasse," Stuttgart, 1911).

of brain indicated that elephants had larger brains; comparison of size per unit body weight, that is, comparison of the ratios brain weight/body weight, indicated that

¹⁶Snell, O., *Arch. Psychiatrie und Nervenkrankheiten*, **23**, 436 (1891).

¹⁷Du Bois, E., *Bull. Soc. Anthropol. Paris*, **8**, 337 (1897). Du Bois, E., "On the relation between the quantity of brain and the size of the body in vertebrates," *Proc. Koninklijke Akad. Amsterdam*, **16**, 647 (1914), also **20**, 1328 (1918).

¹⁸Lapicque, I., *C. R., Soc. Biol.*, **50**, 62 (1898), and many papers since then. See especially Lapicque's chapter on the relation between brain weight and intelligence in "Traite de psychologie," Paris, 1922.

Fig. 17.14c. Juvenile growth in height of children is linear while weight growth is exponential (Fig. 16.50 and 16.52).

elephants had smaller brains and rats larger brains than man. Species comparisons of brain weights cannot be accomplished, therefore, by comparing absolute brain weights or by comparing the ratios of brain weight to simple body weight.

They next compared the power of brain weight to a power of body weight as indicated by the equation

$$Y_1:Y_2 = X_1^b:X_2^b$$

Fig. 17.14d. When prenatal weight growth (solid circles) in man is at a constant percentage rate, sitting-height growth (open circles) is linear. (From data by G. L. Streeter, Carnegie Inst. Washington, Contribution to *Embryology*, 11, 143 (1920).

in which Y_1 and Y_2 are the brain weights of animals 1 and 2, having body weights X_1 and X_2 .

The exponent b is evaluated by taking logarithms:

$$\log Y_1 - \log Y_2 = b \log X_1 - b \log X_2$$

whence

$$b = \frac{\log Y_1 - \log Y_2}{\log X_1 - \log X_2}$$

DuBois and Lapicque demonstrated in 1895 that the value of b was practically the same, of the order of 0.56, for many pairs of brain-body ratios of mature animals of different species, but only 0.25 for mature animals of the same species.

Lapicque, moreover, plotted the logarithms of brain weight against the logarithms of body weight and found that the distribution of the data is linear, having a slope of 0.56. He found that while the slope was always 0.56 for each of a number of series of animals, yet each of these closely related series of animals had a different intercept from other groups. That is, in the equation $Y = aX^b$, the numerical value of b was the same

Fig. 17.15. The relation of weight to linear size in Jersey, Holstein, Guernsey, and Ayrshire cattle plotted on logarithmic coordinate paper.

for each of the series; but the numerical value of a , that is, the ratio $\frac{Y}{X^b} = a$, was highest for man; next for the anthropoid apes, and so on down the supposed scale of evolution.¹⁹

¹⁹See Table 17.1, p. 642, and the charts for brain weights of different species. They show that a 60-kg man has about ten-fold the brain size of a 60-kg sheep—about 1500 gm, as contrasted to about 150 gm. Brain weight in man is about 1/40 of the body weight and 1/400 in other species of equal body weight. 1000-lb cattle have a brain weight of only 400 gm, horses 650 gm, and so on. Man's brain is almost as large as the elephant's (Fig. 10.1). In common words, a 150-lb man has a 3-lb brain; a 150-lb sheep has a 1/4-lb brain; a 1500-lb cow has a one lb brain.

This discovery at once solved one of the great puzzles in anthropology, namely, why the ratio of brain size to simple body size of a fowl, for example, was as great as that of man.

Summarizing, Snell, DuBois, and Lapicque have shown that the proper method of comparing brain size to body size in animals of different size is not to evaluate the ratio of brain weight to simple body weight, but the ratio of brain weight to body weight

Fig. 17.16. The relation of weight to linear size in Jersey and Holstein cattle plotted on arithmetic coordinate paper. The numerals refer to the ages in months. Compare to Fig. 17.15 representing similar data on logarithmic paper.

raised to the b th power; and this ratio, a , the so-called "cephalization coefficient", in the equation $a = \frac{Y}{X^b}$, tends to vary with the degree of mental evolution. By this method the brain-to-body ratios met their expectation concerning differences in *relative* brain size in different species. The value of a in the ratio $\frac{Y}{X^b}$ is highest for man, a reassuring discovery.

This was, of course, the reasoning employed (Ch. 13) for comparing the metabolism of small and large animals. Thus the ratio metabolism Cal/body weight Kg is nearly

200 for mice and 15 for cattle; but the ratio metabolism Cal/(weight)^b Kg in which $b = 0.73$, is nearly the same, about 70, for both mice and cattle. It was, therefore concluded that the proper physiological reference base for comparing metabolism of mature animals of different species is not simple body weight, X , but the 0.73 power of body weight, that is $X^{0.73}$. As previously noted, dimensional consideration indicates an exponent of 0.67 for geometrically similar animals of different size; but large and small animals are not similar dimensionally.

Fig. 17.17. See caption for Fig. 17.16.

The parabola $Y = aX^b$ has been used in biology for perhaps a century (Ch. 13) and since about 1890 for relating organ weight to body weight. About 1910 Dreyer²⁰ in England and Moulton and associates at the Missouri Station²¹ became particularly ac-

²⁰Dreyer, G., and Ray, W., *Proc. Roy. Soc.*, **82B**, 545 (1910), and many subsequent papers.

tive in its use. However, the impetus to its current popularity came from Huxley's²² and Needham's²³ systematization, and nomenclature of data.

As previously noted, the traditional name for the equation $Y = aX^b$ is parabola (b is positive), hyperbola (b is negative), linear (b is unity). However, name-minded biologists felt that a special terminology should be evolved, and many designations, for example allometry (Huxley and Teissier, 1936), from the Greek *allometron*, "that by which anything is measured", have been suggested. (The allometric equation $Y =$

Fig. 17.18. See caption for Fig. 17.16.

aX^b is one "by which anything is measured"? Since the writer's "competency" level does not react to these name "evocators", he will not discuss them, but proceed with analysis of relative-growth data with the aid of, as termed of old, parabolas, and refer the reader to the original papers for the newer terminology.²⁴

17.4: Relation between organ weight and total body weight²⁵. As explained above, the *relative* or *percentage* growth rates are different for linear size, area size, visceral organs, and total body weight. The extent of these differences in relative growth rate may be investigated by different methods.

Fig. 17.19. While the curves in Figs. 17.15 to 17.18 appear entirely smooth, uneventful, yet if the ratios Y/X^b are plotted against age, trends appear. See, however, Fig. 17.25 representing a much greater body of different data, when trends disappeared.

One method (Figs. 17.1a and c), a qualitative one, consists in comparing outlines or photographs of the animal at different ages; a second method (Fig. 17.1b), semi-quantitative, consists in plotting the given measurements against age on arithlog paper (the slopes of which, of course, represent relative or logarithmic change) and comparing the slopes; or (Fig. 17.1d) plotting the given measurements in terms of percentages of mature size on arithmetic paper and comparing the slopes. The ratio of the slopes represents approximately the value of the exponent b in the equation $Y = aX^b$, as indicated below.

²⁵Brody, S., and Kibler, H. H., Univ. Mo. Agr. Exp. Sta. Res. Bull., 328, 1941.

A third method, illustrated in Figs. 17.2a and b, involves plotting against age the ratio of organ weight to body weight. This method appears simple, but it has disadvantages, one of which is that it is not possible to plot wide ranges of data on the same scale (Fig. 17.2b); another is that the eye is not as sensitive to deviations from a curve as it is from a straight line.

The fourth method, used exclusively in this chapter, attempts to "rectify"

Fig. 17.20. The relations (slope) of weight to height at withers and to chest girth in work horses are almost identical with those in dairy cattle.

the data, that is throw them into a form which gives a straight line on some kind of paper. Thus the parabola $Y = aX^b$, and especially²⁸ $Y = aX^b + c$, is in straight-line form when written logarithmically: $\log Y = b \log X + \log a$. When plotted on log-log paper the data yield a straight-line distribution if the equation represents the data. However, there appear to be changes or "breaks" in the value of the exponent b , especially during early growth, as illustrated in Fig. 17.3. None the less, representation of the data on a log-log grid is the most satisfactory method; it shows how the

²⁸Robb, R. C., *British J. Exp. Biol.*, 6, 311 (1929). Twitty, C., *Symposia on Quant. Biol.*, 2, 148 (1934).

percentage increase in organ weight changes with percentage increase in body weight. The values of the slopes, b , given in Fig. 17.3, were computed by the usual method, $b = \frac{\log Y_1 - \log Y_2}{\log X_1 - \log X_2}$.

Derivation of the parabola $Y = aX^b$ from the exponential growth equation. Preceding the inflection in the S-shaped age curve of growth in weight (self-accelerated phase), the course of growth may be represented by the equations:

$$Y = c_1 e^{k_1 t} \quad (1)$$

$$X = c_2 e^{k_2 t} \quad (2)$$

where Y is the size of one structure; X , the size of another structure; c_1 and c_2 constants; k_1 and k_2 , growth rates; t , time or age. Taking natural logarithms of (1) and (2),

Fig. 17.21. The relation of weight to height in man plotted on logarithmic coordinate paper. The curve appears to have four segments, each having a different slope, n .

$$\ln Y = \ln c_1 + k_1 t$$

$$\ln X = \ln c_2 + k_2 t$$

Differentiating

$$\frac{dy}{y} = k_1 dt \quad (3)$$

$$\frac{dx}{x} = k_2 dt \quad (4)$$

Dividing (3) by (4)

$$\frac{dy}{y} \div \frac{dx}{x} = \frac{k_1}{k_2} \quad \text{or} \quad \frac{dy}{y} = b \frac{dx}{x}$$

where $\frac{k_1}{k_2} = b$ (a constant).

Integrating

$$\log Y = b \log X + \log a$$

and

$$Y = aX^b$$

which is our parabola.

Fig. 17.22. The relation of weight to height and to sitting height; also of sitting height to height, for children in different economic classes, plotted on logarithmic co-ordinate paper. The slopes, n , are indicated on each curve.

It is more confusing to derive the parabola from the equation for the phase of growth following the inflection^{26a} (self-inhibited growth phase).

The inflection in the S-shaped curve of growth in total weight does not necessarily coincide with the inflections in growth of the bodily components or with the age curves of the several linear dimensions. Moreover, the course of weight growth prior to the inflection tends to be exponential, while that of linear growth tends to be linear (see section below on linear growth). It follows that while the parabola $Y = aX^b$ may fit the relation approximately, or for segments of the curve, it cannot represent precisely the $Y - X$ relation for the entire growth period. There must be "breaks" or changes

Fig. 17.24. The central heavy curve represents the average (geometric mean) of all the 15,610 data points. The lighter lines represent the curves from Fig. 17.23, and the standard error of estimate.

in slope in the curve, perhaps insignificant, as was indeed demonstrated by Lumer.²⁷ This parabola is none the less extremely useful.

Let us next picture the situation as a whole: how a set of organs in a given species grows in relation to the body as a whole. Such a general picture is shown in Fig. 17.4 for the growth of man, birth to 20 years of age. From this chart, it will be seen that the brain grows about 70 per cent as rapidly as the body prior to about 6 years and about 7 per cent as rapidly

^{26a} For its derivation, see Univ. Mo. Agr. Exp. Sta. Res. Bull., 262, 1937.

²⁷ Bernstein, F., *Symposia on Quantitative Biology*, 2, 209 (1934); Lumer, H., *Growth*, 1, 140 (1937). Brody, S., Davis, H. P., and Ragsdale, A. C., Univ. Mo. Agr. Exp. Sta. Res. Bull., 262, 1937.

thereafter. The slope declines from about 70 to about 7 per cent, an enormous "break".

The curve for the liver also appears to show a break at about 6 years.

Fig. 17.25. The nature of the fluctuations in the ratio $\frac{\text{weight}}{(\text{chest girth})^b}$ for the data in Fig. 17.23 indicates that either there are no biologically-significant systematic deviations from the parabolic trend $Y = aX^b$, or that the fluctuations are masked by compensation. See, however, Fig. 17.19 representing a different set of data.

With the exception of heart, thyroid, and spleen, the relative increase in the weight of the visceral organs is less than that of the body as a whole.

The gonads and adrenals follow a parallel course: they rise, first slowly then rapidly, on to the advent of puberty. It did not seem worthwhile to fit equations to the data. The gonads in rabbits^{27a} increase during a certain

^{27a}Kibler, H. H., Bergman, A. J., and Turner, C. W., *Endocrinology*, **33**, 250 (1943).

age interval, with the X^2 for females and $X^{2.8}$ for males; the adrenals in the same rabbits increased with $X^{0.9}$ for both males and females (X = body weight). A curious feature of the rabbit adrenal curve is that at about 2.5 kg body weight (beginning of sex activity), there is an increase in slope of the adrenal curve; the adrenal weight then increases with $X^{1.78}$ instead of with

Fig. 17.26. The relation of body weight to height at withers. Note that the fit of the parabola $Y = aX^b$ is not as good for the weight to height as for the weight to chest girth.

$X^{0.94}$ (Fig. 17.5b). The same results were obtained on guinea pigs (Fig. 17.5d).²⁸ This sudden increase in adrenal weight may be associated with a corresponding acceleration in protein catabolism²⁹, and hence with a decline in growth rate at this time. Some animals also show a steep rise in the kidney weight at this time (Fig. 17.5e).

Fig. 17.4 thus indicates the general course and the order of change of organ weight with increase in body weight during growth, the nature of the breaks in the curve, the nature of changes in "atypical" curves, such as of

²⁸Mixner, J. P., Bergman, A. J., and Turner, C. W., *Endocrinology*, **32**, 298 (1943).

²⁹Cf. Long, C. N. H., "Cortical hormones and metabolism," *Endocrinology*, **30**, 870 (1942). Turner, C. W., Personal communication.

the gonads and adrenals, and incidentally gives an idea of the weights of the various organs.

As explained above, the value of the exponent, b , in the equation $Y = aX^b$, varies with age and with other factors. Fig. 17.6 shows the values of b for various organs in dairy cattle, in this case all mature, and ranging in body

Fig. 17.27. Wool weight as function of body weight.

weight (at the slaughter house) from 800 to 1600 lbs. Here the slope b is very low for all organs. Thus the heart varies with $X^{0.56}$ rather than with $X^{1.02}$, as in growing man (see Table 17.1).

So far we discussed the relation of organ weight to body weight in the same species. Fig. 17.7 shows the relation of organ weight to body weight in mature mammals (heavy lines) and birds (light broken lines) of different species. The slopes, b , are given on the chart (see Table 17.4).

Fig. 17.7 shows that for mature mammals of different species, the basal heat production increases with the 0.73 power of body weight; the brain weight increases with the 0.70 power of body weight, virtually the same as for basal heat production; the pituitary increases with the 0.76 power of body weight; the adrenals with the 0.80 power, and so on. Without exception the visceral organ weights in *mature animals of different species*³⁰ increase

Fig. 17.28a. Feather weight, F , in chickens plotted against body weight, M .

with a fractional power of body weight, that is, the weights of visceral organs do not increase as rapidly as the body as a whole.

³⁰The most important, indeed monumental, collection of data on organ size is given by Crile, George, and Quiring, D. P., *Ohio J. Soc.*, 40, 219 (1940).

The most conspicuous feature is that the slope of the curve relating brain weight to body weight is virtually the same as the slope relating basal heat production to body weight. This means that the ratio metabolic rate/brain

Fig. 17.28b. Feather weight, F, plotted against body weight, M.

Fig. 17.28c. Feather number and feather weight per unit surface area, plotted against body weight.

weight tends to be the same for small and large animals; the ratio metabolic rate/body weight, on the other hand, declines rapidly with increasing weight.

Does this close *statistical* correlation imply the presence of a similarly close *causal physiological* interrelation between brain weight and metabolism?

Fig. 17.28d. See caption for Figs. 17.28a and b.

Fig. 17.29a. Thyroid weight in different species (Brody and Kibler, *l.c.*).

It may be so. It is known that the blood supply to the brain—about 13 per cent of the cardiac output (Barcroft and others)—is all out of proportion to the relative weight of the brain. Kestner³¹ estimated that under *basal metabolism* conditions nearly half of the blood passes through the brain. Hence Kestner's conclusion that under basal metabolism conditions the brain probably conditions the level of basal metabolism.

Fig. 17.29b. Thyroid weight in guinea pigs (Mixner, Bergman, and Turner, *l.c.*).

Crile³² emphasized the metabolic importance of the brain: "The brain is the universal executive of energy and is adaptively controlled by the thyroid glands for its constant

³¹Kestner, O., *Proc. Physiol. Soc.* (1935), in *J. Physiol.*, **87**, (1936).

³²Crile, G., "A neuro-endocrine formula for civilized man," Reprint from "The Educational Record Supplement" for Jan. 1941, Am. Council Education, Washington, D. C.

energy and by the adrenal gland for its emergency energy. Throughout the animal kingdom the primary role of the brain is to maintain body temperature and to drive the muscles and organs in attack and escape. It is the function of the brain alone to execute the oxidation for the long and short swings of both the thyroid and the adrenal glands. We found that it requires 1 gram of brain to execute 12.115 Calories in twenty-four hours."

Fig. 17.30a. Parathyroid as function of body weight, by Campbell, I. L., and Turner, C. W., Mo. Agr. Exp. Sta. Res. Bull. 352, 1942.

The influence of environmental temperature, and consequently of the level of heat production, on size of brain was demonstrated in a spectacular manner by Crile and Quiring³³ on two animals of the same weight, namely a 521-kilogram horse and a 521-kilogram White or Beluga Whale. The total daily heat production must be greater in the whale than in the horse, because sea water conducts heat 27 times as rapidly as air, and moreover the water in which the whale lives is below 0°C, much lower than the average air temperature in which the horse lives. The whale, generating more heat than the horse, has a brain 2.9 times and a thyroid 3.2 times larger than the horse. Hence the casual relation of brain and thyroid to heat production, and the conclusion that

³³Crile, G., and Quiring, D. P., "The energy releasing organs of the white whale and the thoroughbred horse 'Equipoise'," *Growth*, 4, 291 (1940).

certain of the visceral organs, especially the brain, are "energy activators".⁸⁴ However, while the human brain is the largest, 10-fold the size in a sheep of the same body weight, yet the basal metabolism of man is less than of a sheep.

Fig. 17.30b. Location of parathyroids in the rabbit, by Campbell and Turner, *l.c.*

⁸⁴The following table from Crile illustrates the influence of environmental temperature on relative weight of brain, thyroids, adrenals, and the heart.

Animal group	Brain	"Relative Size"		Heart
		Thyroids	Adrenals	
Tropical rodents10	.09	.44	.11
Northern rodents13	.20	.72	.13

Tropical ungulates65	.41	.29	.36
Northern ungulates70	.43	.29	.52
Cetacea	2.30	1.60	.37	.37

We next discuss charts relating individual organs to total body weight. All the charts are on logarithmic paper; the mature *mammals of different species* are represented by heavy continuous lines, the mature *birds of different species* by heavy broken lines; the animals of the same *species* of different

Fig. 17.31. Kidney weight. See also Fig. 17.5e (page 589).

weight, growing or mature, by lighter continuous curves labelled (GR). The very light broken lines on each side of the heavy continuous lines (for mature mammals of different species) represent the standard errors of estimate, S_r , which include between them two-thirds of the data points. The average line represents $Y = aX^b$ fitted to the data by the method of least squares. The constant ρ , the index of correlation, has the same significance for these curves as the constant r , the coefficient of correlation, for linearly related data. The given data points (circles except where otherwise indicated for a special reason) represent mature animals of different species only. (The data points for the birds and growing animals of the same species are omitted in the interest of legibility.) Each of the data points is the average of a number of animals. The number and sources of data are listed in the appendix.

The "prediction" values (computed from the fitted equations) for organ weight corresponding to given body weight are also given in the appendix.

Brain weight: There are more data on the weight of the brain than on any other organ because of its human interest. Fig. 17.8a presents some of

Fig. 17.32. Liver weight.

the available data on the relation of brain weight to body weight plotted on logarithmic paper (see also Fig. 10.1).

As previously noted, the brain weight in mature mammals of *different species* varies with approximately the 0.70 power; that is, doubling body weight increases brain weight about 70 per cent. The values of $+S_r$ and $-S_r$ indicate that two-thirds of the data fall between $+64$ and -39 per cent of the average curve. The index of correlation, which is 0.97, is very satisfactory. The value of the exponent for birds is considerably less than for mammals, meaning that, in comparison to small birds, large birds have relatively smaller brains than mammals.

The other curves and equations in Fig. 17.8a represent the brain-body relations of animals in various stages of growth. Except for the early stages of growth (see the 1 to 15-day interval post-natal growth in the rat, in the upper-left insert chart), the slopes of these curves (for animals of the same species) are usually very much lower than for mature animals of different species, the exact values depending on the period of growth. The later the period of growth, the lower is the slope. In general, as noted by Du Bois and Lapicque, the post-natal slope relating brain to body in the same species is near 0.25.

Fig. 17.33. Lung weight.

Note that the brain weights of small whales (triangles), of Simians (X's), and especially of man (black circles), are very much above the average line, whereas those of large whales are below the average. These species were not included in computing the equation represented by the curves.

Summarizing for mature animals of different species, the slope of the curve relating brain weight to body weight parallels the slope of the curve relating

basal metabolism to body weight. The values of slopes relating brain weight to body weight in growing animals of the same species depend on the growth period; the younger the animal the steeper the slope. During the later periods of growth, for which most data are available, the slopes are very much below those for mature animals of different species.

Pituitary weight: Few data are available on the pituitary weight. Because of the importance of this organ, the few available data are charted in

Fig. 17.34. Stomach and intestine weight.

Figs. 17.9a, b, and c. It appears that the slope relating pituitary weight to body weight in mature animals of different species, 0.76, is quite close to the slope of the curve relating basal metabolism to body weight, 0.73. The slope is somewhat less for post-natally growing animals within the species.

As with brain weight, age is an important factor conditioning the slope of the pituitary curve of animals of the same species.

Heart weight: As previously indicated, the metabolic level depends on the interrelation of several systems, including the stimulating or afferent (neuro-endocrine) system, and the receptive or efferent (cardiovascular) or

operating systems. The brain and pituitary discussed above exemplify the stimulative system; the heart discussed in this section exemplifies the receptive or operating system.

The heart weight is correlated with the exercise level of the species and individual. This is illustrated in Fig. 17.10. Aquatic animals invariably have relatively smaller hearts than terrestrial animals because their weight is counterpoised by the weight of the water they displace; they are not obliged

Fig. 17.35a. It is shown in Fig. 17.1c that body weight is very sensitive to food supply, chest girth is less sensitive to food supply, and height at withers in cattle is virtually unaffected by food supply. Hence height at withers is the best index of the genetic size of the animal, independent of food supply. Fig. 17.35a by W. H. Black, B. Knapp, Jr., and A. C. Cook [*J. Agr. Res.*, 56, 465 (1938)] brings out the same idea in a different way: the ratio of weight to height at withers gives the highest correlation with "performance" (gain in weight). Fig. 17.35b brings out the same idea in a still different way: 50 per cent of height at withers (measurement #1) is completed before birth as contrasted to 6 per cent of body weight. Hence food supply does not have the opportunity to affect height at withers (measurement #1) as it can weight or chest girth (#18, see Table 1) the second most easily measured linear dimension. While 17.35b shows percentage of mature size at birth, Fig. 17.35c shows multiples of birth size. Thus hip width at 5 years (virtual maturity) is 3.3 times or 330 per cent times the heart girth at birth. These 3 charts are for cattle.

to overcome the pull of gravity, as are terrestrial animals which must make successive liftings of the body against gravity when walking or running. Likewise, terrestrial animals, known for their running ability, such as horses and dogs, have relatively larger hearts than domestic pigs or guinea pigs.

Similarly, as might be expected, the heart weight tends to vary more directly with body weight (rather than with basal metabolism) during growth than would other visceral organs, such as the neuro-endocrine, because the work performed by the heart in walking varies directly with the body weight.

Fig. 17.35b. See caption for Fig. 17.35a; also Fig. 17.11 and Table 17.7.

In other words, the slope, b , of the curves relating heart weight to body weight is in many cases very close to unity, as shown in Fig. 17.10; still, especially as shown in the insert on the upper-left corner of Fig. 17.10b, it is much better to relate heart weight to body weight by the power equation $Y = aX^b$, than by the linear equation $Y = a + bX$.

Other visceral organs: The foregoing discussions of the typical visceral organs—brain, pituitary and heart—are applicable, with slight variations, to practically all other visceral organs. The charts for the other visceral organs

in relation to body weight are therefore presented in the appendix without much discussion.

To summarize, the slope relating metabolism to body weight parallels the slope relating the weight of some neuro-endocrine organs to body weight. The weight of the heart, on the other hand, tends to vary more directly with body weight (slope near unity) as the work performed by the heart in locomotion tends to vary directly with body weight. For direct agricultural applications concerning the relation of muscular and fat tissues to visceral tissues, see Hammond⁹ and text books on stock judging.

Fig. 17.35c. See caption for Fig. 17.35a, b.

17.5: Linear growth and form. Age change in form is, of course, associated with differences in growth rates in different directions. As explained in the preceding section and illustrated by Figs. 17.1a to d, change in form may be observed (1) *qualitatively* by comparing outlines or photographs of the animal at different ages; (2) *semi-quantitatively* by comparing the slopes of the age curves of growth in various directions, and (3) *quantitatively* by fitting the relative-growth equation, that is, the parabola $Y = aX^b$, to the data after first plotting Y against X on a log-log grid and noting the nature of distribution of the data.

While the age curve of growth in weight describes the change in the *organism as a whole*, the age curve of growth of some one linear dimension describes the change in only one of many linear measurements, which may or may not be proportional to the change in other linear measurements or to the change in weight. Thus (Fig. 17.1c) the post-natal growth of the rabbit cranium is no index of the post-natal growth of other linear measurements or of the body as a whole, for all the photographs were reduced to the same cranium size.

The same may be said with regard to several other comparative outlines in Fig. 17.1. In other words, higher animals grow not in one, two, or three different linear dimensions, but in many. The concept of *n*-dimensional change is now generally understood. This, of course, is the reason why weight cannot be expressed exactly as the cube of some *one* linear measurement, or that surface area cannot be represented as the square of some *one* linear measurement, or even as the $\frac{2}{3}$ power of weight, which represents all the *n*-linear dimensions and which should, therefore, be something of an average.

Then too, weight (volume) growth prior to puberty tends to be self-accelerating, that is, to grow in a *geometric* progression (one cell giving rise to 2, 2 to 4, 4 to 8, 8 to 16, etc.) and to plot linearly against age on *arithlog* paper, at least for short periods, whereas linear growth, *i.e.*, terminal growth, tends to grow in an *arithmetic* progression, according to the series 1, 2, 3, 4, etc., and to plot linearly on arithmetic paper. There is an inflection in both cases, but the inflection is likely to occur at different ages, for example, earlier for the length of the rabbit cranium than for the length of the rest of the body (Fig. 17.1c), and still earlier than for the total body weight.

17.5.1: Age curve of linear growth. In view of the nature of linear growth, complicated by the fact that there is not one but *n* linear dimensions, each growing at a rate different from the others, it seems desirable to examine a few linear age curves of growth before proceeding with the fitting of the parabola to the relation of linear size to weight.

Most of this analysis relates to dairy cattle measured at the Missouri Station by Eckles, Ragsdale, and associates³⁵ and at the Nebraska Station by Davis, Morgan, and associates.³⁶ The data on man are from the literature.

Fig. 17.11 shows the measurements taken and the numbers by which they are referred in the text. Table 17.7 names each of the measurements and gives the numerical values of the constant *A* (mature size), 100*k* (percentage decline in growth rate per month), and the ages at which various fractions of *A* are attained (see Ch. 16 for details).

Tables 17.8 and 17.9 give the numerical values of the measurements plotted in Figs. 17.12a and b. The agreement between observed and computed values

³⁵Brody, S., and Ragsdale, A. C., Univ. Mo. Agr. Exp. Sta. Res. Bulls., 80, 89, and (with H. P. Davis) 262.

³⁶Davis, H. P., Morgan, R. F., Brody and Ragsdale, Univ. Neb. Agr. Exp. Sta. Res. Bull., 91, 1937.

is satisfactory for each of the linear measurements growing at a different relative rate ($100k$) from every other linear measurement. The exponential equation $L = A - Be^{-kt}$ (Ch. 16) may thus be said to represent the "ground plan" of the later linear growth, as indeed of weight growth.

Fig. 17.13 shows that this equation also represents linear growth in man following puberty. While the maximum height, A , ranges from 153 to 172 cm, and the value of $100k$ ranges from 45 to 82 for the various groups, they may all be represented by the same equation, $L = A - Be^{-kt}$; they all have the same basic growth plan.

So much for the later (self-inhibiting) phase of linear growth.

Now as regards the earlier phase, prior to the inflection, Fig. 17.14a shows that in cattle, when weight growth has an increasing slope (geometric progression) on arithmetic paper, linear growth has a constant slope (arithmetic progression). Fig. 17.14b shows a similar situation for the growth of man.

Summarizing, in early life when weight growth tends to occur in a geometric progression, or exponentially, linear growth tends to occur in an arithmetic progression, or linearly. Following puberty, both weight and linear growth decline exponentially, as indicated by the excellent fit of the equation $L = A - Be^{-kt}$ to the data.

17.5.2: Relation between linear and weight growth. As previously explained, the applicability of the parabola $Y = aX^b$ is determined by plotting Y against X on a log-log grid, and estimating the value of b by measuring the slope of the line drawn through the data by inspection; or if desired, this equation may be fitted to the data by the method of least squares (Ch. 13). Figs. 17.15 to 17.18 represent weight plotted against some linear size with the slope, b , estimated by inspection. Note from Fig. 17.15 that the distribution is linear on the log-log grid³⁷, indicating that the parabola fits the data.

Figs. 17.16 to 17.18 illustrate how such data appear when plotted on arithmetic paper. Here the curve rises as expected from the fact that weight growth tends to vary with the cube (third power) of linear growth. However, as indicated by the equation, the slope is not 3, but it ranges from 2 for the relation of weight to width of hips, 3 for the relation of weight to chest girth, and 4 for the relation of weight to height at withers. The chest girth thus comes nearest to being the theoretical average of linear growth—to meeting the dimensional-analysis expectation that weight varies with the cube of linear size.

While the distribution of the weight to linear size data appears to be uneventfully smooth in Figs. 17.16 to 17.18, if the ratios weight/(linear size) ^{b} are plotted against age, as shown in Fig. 17.19, with the corresponding values of the exponent b given in Figs. 17.16 to 17.18, the resulting curve shows systematic variations. This substantiates what was previously said about

³⁷Fig. 17.15 from Ragsdale, A. C., Regan, M. J., and Brody, S., Univ. Mo. Agr. Exp. Sta. Res. Bull., 142, p. 13, 1930. The other charts plotted from Tables 17.8-10 and 17.15.

the capacity of the parabola $Y = aX^b$ to swallow up in the general trend small though significant differences in rate and method of growth.

What was said about the relative-rate of growth of cattle probably holds true of other grazing animals, for example, horses, as indicated in Fig. 17.20. The numerical values of the slope, b , for growing horses is nearly the same as for growing cattle.

The relative-rate of growth of humans shows an opposite extreme as illustrated in Figs. 17.21 and 17.22. The relation of weight to height in humans shows conspicuous breaks in the curve at 1, 5, and 15 years, the last two ages corresponding to the beginning and end of the juvenile period, and the first the end of the exclusive dependence on milk. (Compare with Figs. 16.7, 16.50, 16.52 and especially 17.1e.) Moreover, proportional growth at different ages in humans is in many respects different from that in horses and/or cattle. Thus in humans, leg length is relatively slow prenatally and most rapid during the juvenile period (Fig. 17.1); in cattle and horses, practically all the leg-length growth is completed before birth. The parabola does not, therefore, represent the relation of weight to linearly measured complexes as satisfactorily in humans as it does in cattle and horses, but it is the best equation available for analytic as well as predictive purposes, which we consider next.

17.6: Estimating weight of cattle from chest girth. Dairymen do not often have scales for weighing cattle; yet weight is very important for estimating feed needs, energetic efficiency, and monetary profit from milk production (Ch. 22) and growth. The apparently satisfactory applicability of the parabola $Y = aX^b$ to the relation of weight to chest girth (Figs. 17.15, 17.16, 17.23, 17.24) suggested the idea of employing the equation for predicting weight from chest girth³⁵. Accordingly, this parabola was fitted, by the method of least squares, to 15,610 pairs of body-weight and chest-girth measurements of dairy cattle of all ages owned by the Missouri and Nebraska agricultural experiment stations,^{35, 36} with the results shown graphically in Fig. 17.23.

The heavy line represents the fitted parabola; the light broken lines, the standard errors of estimate, $+Sr$ and $-Sr$, between which are included two-thirds of the data. The constant, ρ , for the logarithmic relation corresponds to the coefficient of correlation, r , for arithmetical relations.

All the curves in Fig. 17.23 were brought together for purposes of comparison in Fig. 17.24. The outside broken lines represent the standard error of estimate of all the data.

Figs. 17.23 and 17.24, which include 15,610 weight-chest measurements, represent 6 sets of data: 2454 measurements on Missouri Holstein cattle; 2235 Missouri Jerseys; 5866 Nebraska Holsteins; 2758 Nebraska Jerseys;

³⁵The chest girth is easily measured by placing the tape about 6 inches back of the front legs.

840 Nebraska Guernseys; and 1457 Nebraska Ayrshires. A close examination of the curves in Fig. 17.24 indicates that during the earlier periods, the Nebraska cattle, particularly the Holsteins, are heavier for a given chest girth than the Missouri. This difference is attributed to the higher nutritional level of the Nebraska calves and to the greater influence of a high nutritive level on weight than on chest girth. While the difference is significant statistically, it is probably not so practically.

For purposes of comparing the degree of agreement between observed and computed weights, "observed" weights were obtained by grouping the chest-girth values into 1-inch intervals, *disregarding age*, and computing the geometric means³⁹ of the weights for these 1-inch chest-girth intervals. These "observed" means are compared in Table 17.10 to those computed from the fitted parabola.

An attempt was made to improve the predictive values of chest girth by sorting the data by ages into month intervals, then relating weight to chest girth for each month separately. The results are shown in Tables 17.11 to 17.14 in the appendix.

While including age in the prediction table improves the prediction value of the chart, the following shortcomings of the age-girth-weight prediction charts may be pointed out:

(1) Dividing the data by age classes reduces the number of data in each class, and consequently reduces the regularity of distribution of the data.

(2) As a result of (1), the fit of the parabola $Y = aX^b$ to data and its prediction values become less certain.

(3) The numerical value of b of the parabola, when thus fitted to the reduced data, is not near 3, as found when the data are grouped by chest girth regardless of age, but is near 2, a result which is very disturbing from the viewpoint of dimensional analysis, and suggests further investigation.

(4) Difference in feed supply probably affects predictions obtained on the basis of age classes to a different extent than when age is overlooked. This problem obviously calls for further intensive study.

From the above considerations it is not safe to advise which method of prediction should be used, that in Table 17.10, ignoring age, or that in Tables 17.11 to 17.14, including age. The dairyman will simply have to check each of the tables on the animals in his herd, and use the ones which give best agreement with his own measurements.

The use of Table 17.10 for prediction is simple: measure the chest girth and read the weight from the column representing a given breed, or from the grand average. This is perhaps the best method, although no doubt special gadgets, slide rules, etc. may be devised for this purpose. There is need for a good tape measure, one which will withstand the rough handling without stretching, shrinking, curling, and breaking.

To estimate weight from Tables 17.11 to 17.14, measure chest girth, note the age of animal, and read the weight corresponding to the given chest girth and age. The bold-face values represent the averages of the measured animals.

The following are additional comments in favor of employing chest girth and the logarithmic equation for predicting weight:

³⁹ There is no practical difference between *geometric* and *arithmetic* means for the given narrow chest-girth intervals. The geometric means are probably theoretically superior to the arithmetic means because of the geometric or logarithmic relation between weight and chest girth.

(1) From the viewpoint of dimensional analysis, chest girth comes nearest to being representative of the linear size of the animal as a whole because the numerical value of the exponent b in the parabola is nearest to 3. This means also that weight growth is most closely correlated with chest-girth growth.

(2) If the ratio weight/(chest girth)³ is plotted against age, as shown in Fig. 17.25, it does not exhibit the same consistently systematic deviation from the average in all groups. The fact that the trends vary from group to group indicates that they are probably caused by management (feeding) conditions. Thus the Nebraska curves show high, and the Missouri curves low initial ratios. The group differences in weight at given chest girth levels indicate that the relation between weight and chest girth is in part dependent on nutritive condition: a relatively high nutritive level at the early ages causes a relatively (with regard to the equation level) greater weight increase than chest-girth increase, presumably because of relatively greater weight deposition in other regions than around the chest.

(3) While the precision of the measurements is arithmetic, that of the fit of the equation is logarithmic. Now it can be shown that in the equation $Y = aX^b$ and its logarithmic form $\log Y = \log a + b \log X$ the precision of $\log Y$ is Y times the precision of Y ; therefore the predictive reliability is better when employing a logarithmic equation fitted logarithmically, as was done in this section, than when employing an arithmetic equation fitted arithmetically.

(4) It may be noted, as is generally known, that weight measurements, Y , can be made with greater precision than linear measurements, X . Account should be taken of these differences in precision of measurements in fitting the equation;⁴⁰ this was not done. However, of all the linear measurements taken of cattle, those of chest girth probably involve least error, and therefore give best predictions for body weight.

Summarizing, this section presents an important practical application of the parabola $Y = aX^b$: a vast body of data (15,610 animals) representing four breeds of cattle of all ages and conditions at the Missouri and Nebraska Stations were welded together by this parabola for the purpose of preparing a thoroughly representative and reliable table for estimating weight from chest girth of dairy cattle of unknown (Table 17.10) or known (Tables 17.11 to 17.14) ages. Statistical analysis indicates that changes in chest girth and weight in cattle are particularly well correlated, and that when using the average curve in Table 17.10, two-thirds of the prediction over the whole range of data may be expected to fall within ± 13 per cent of the average. Theoretically, closer prediction may be expected if the breed prediction table is employed, and still closer if the breed-age-chest girth-weight tables (17.11 to 17.14) are employed. Of all the linear measurements investigated, chest girth in growing cattle appears to be most closely correlated with body weight, and is most nearly representative of the linear size of the animal. This is indicated by the fact that weight varies most nearly with the cube of chest girth. This means that an increase in chest girth by 1 per cent is associated with an approximately 3 per cent increase in body weight.

17.7: Estimating nutritive condition of cattle from height at withers. Nutritive condition in the sense of underweight or overweight is an impor-

⁴⁰Deming, W. E., U. S. Bureau of the Census, Washington, D. C., Personal communication.

tant factor in the efficiency complex (Ch. 5). It is, therefore, important to have a method for measuring the nutritive condition of an animal in comparison to a standard, for example, the average condition of cattle of the breed.

It was demonstrated in the preceding section that chest girth is one of the linearly measured complexes most closely correlated with body weight. Height at withers, on the other hand, is one of the measurements least correlated with body weight. This is demonstrated in Fig. 17.1b, in which the weights, chest girths, and heights at withers are plotted against age on arithlog paper. At age 3 years, the weight of the full-fed group I is over twice that of the underfed group II; the chest girth of the full-fed group I is correspondingly greater than of the underfed group II; but the height at withers of both groups of cattle is virtually the same. Height at withers in cattle is not easily influenced by nutritional conditions, partly because over half of this linearly measured complex is completed by the time the animal is born.

It therefore seemed that height at withers would make an ideal reference base for estimating the degree of fleshiness of an animal in comparison to her own ideal size, or at least in comparison to the average animal of her breed. Thus, if a given Holstein having a height at withers of 52 inches weighs 1100 pounds, and the ideal Holstein (of the same age if possible) weighs 1000 pounds, the given animal is 100 pounds, or 10 per cent, overweight.

The problem of this section is to weld together a large body of data on the relation of weight to height at withers with the aid of the parabola $Y = aX^b$ in the same manner as was done in the preceding section on the relation of weight to chest girth, employing the same animals. The results are shown in Fig. 17.26. The corresponding numerical predictions relating weight to height, without reference to age are given in Table 17.15. The predictions of weight to height at withers including the age factor are given in Tables 17.16 to 17.19. These tables are based on the Nebraska data. The Missouri and Nebraska data do not agree as well for this height-at-withers relation as for chest girth. This very disagreement testifies to the sensitiveness of height at withers as a reference base for estimating the nutritive state of cattle. The two stations feed the animals on somewhat different planes, with consequent differences in the ratios.

Summarizing, this section presents another practical application of the parabola $Y = aX^b$, namely for predicting nutritive condition from height at withers of cattle. The weight of growing cattle varies not with the cube of linear size, as was previously found for the relation of weight to chest girth, but more nearly with the fourth (4.3) power. This means that increasing height at withers by 1 per cent tends to increase body weight by approximately 4 per cent. In other words, height at withers in growing cattle is very much less influenced by increase in body weight than is chest girth. This fact is illustrated in several ways in the text. The fit of the parabola $Y = aX^b$ is not as satisfactory in relating weight to height at withers as it is in relating weight to chest girth.

17.8: Note on the relation of weight to height in humans. Because the growth curves of humans are more complicated and variable than of cattle, the method of assessing body build and nutritional status of cattle is not satisfactory for humans.

Many indices of body build and of nutritional status of children have been published.⁴¹ In Europe one usually hears of the "baric index",⁴² which is 100 times the ratio of weight to the cube of height ($100 \times \text{weight}/\text{height}^3$), or what is equivalent, the "ponderal index", $100 \times \text{weight}^{\frac{1}{3}}/\text{height}$.

As previously explained, weight rises with the cube of linear size, or the cube root of weight rises with the linear size in geometrically similar bodies, which human bodies are not. These indexes do not seem to the writer to be rational.

The common index in this country is weight for given height and age.⁴³ Davenport⁴⁴ suggested that "for young adult males the best index of build is apparently obtained by dividing weight by the square of stature". (Figs. 17.21-2 indicate the reason for the difficulties in finding one overall value of b in the index of build Y/X^b for man.)

Wetzel⁴⁵ gave the best expression to the weight-height-age status. The usual three measurements are taken (height, weight, and age), from which Wetzel estimates body build, developmental level, nutritional level, basal heat production, and dietary caloric needs with the aid of his chart. Wetzel's grid is a weight-height surface flanked by a series of isodevelopmental "channels", probably fractions or multiples of the standard error of estimate.

The use of Wetzel's chart involves taking a series of measurements of the same child at least twice, thus considering "the individual child in relation to his own past record of progress". The outstanding feature of Wetzel's method is that it permits estimation of normality of body build by the degree of parallelism of the weight-to-height curve of the given child to the standard weight-to-height curve plotted on a logarithmic grid. The child's nutritional condition progresses normally if his weight-to-height curve parallels the standard, although it may be some distance above or below the standard. The child tends toward obesity or malnutrition if his weight-to-height curve is, respectively, more or less steep than the average. It is, of course, conceivable that the child's curve may parallel the standard, yet be obese or emaciated, when the same degree of obesity or malnutrition is maintained throughout growth. Likewise, a rise or decline in the slope of the weight-to-height curve may represent approach to normal from malnutrition or from obesity, respectively. In other words, this method, like other methods of assessing normality, is a valuable aid to, but not a substitute for, judgment.

Wetzel's grid stresses the idea that children of different body build tend to parallel (rather than to coincide with) the average course of the weight-to-height curve. This

idea was stressed by others,⁴⁶ but Wetzel's unique contribution is the design of his chart; it brings together the weight, height, age, and also metabolism data into one conveniently designed chart. The weight-to-height zone is divided into seven "physique channels" above and below the standard or middle line, *M*, labelling each line or channel, and explaining that "healthy development continues in an established channel as though this were a preferred path"; in other words, the weight-to-height curve of a normally growing child parallels the standard curve.

The position and slope of a given child's curve below or above the average indicates his relative body build or nutritional level and his trend to average, stock, stout, plump, obese, thin, or slender.

These "physique channels" are connected by lines called "isodevelopmental levels" to a panel on the right side giving a series of "auxodromes" (Greek, course of growth). The body weight and body build or "nutritional" status (weight-to-height) are thus related to chronological age, or to "developmental age"; corresponding to the position, including two-thirds of the children in the given weight class) and also to basal metabolism.

Wetzel notes that the onset of the menarche, which occurs on the average at age 13.6 years,⁴⁷ is correlated with "the final deceleration of growth in weight. . . in the neighborhood of the greatest upper curvature".

17.9: Estimating the amount of wool or feathers from body weight.

Assuming: (1) that the major function of the body covering of hair, wool, and feathers is the regulation of heat loss from the body; (2) that heat loss is proportional to surface area; and considering that (3) hair and feathers have their anchorage in the surface area of the body, it is logical to expect that the *amount* of wool and feathers would be proportional not to body weight but to the surface area of the body. Unfortunately there is some uncertainty as to what biological unit of *amount* of hair or feathers one should adopt. Should it be the *number* of hairs or feathers? There are objections to number as unit of covering, because the length and structure of the individual hairs or feathers vary. There are, likewise, objections to *weight* as unit of covering because, especially in feathers, the structural part, such as the quill, is a very substantial part of the feather weight, yet its heat-regulating function is probably slight.

Lacking rational units of "amounts" of hairy or feathery covering, *wool weight*, *feather weight*, and also *feather number* were related⁴⁸ to *body weight* and also to *surface area* by the parabola $Y = aX^b$, with results shown in Figs. 17.27 and 17.28a to c.

In *yearling* Shropshire sheep, wool weight is practically proportional to surface area. Both vary with approximately the 0.5 power of body weight. In older animals, however, wool weight does not increase as rapidly as surface area. Unlike wool weight, feather *weight* is almost directly proportional to

⁴⁸Brody, S., and Campbell, J., *Univ. Mo. Agr. Exp. Sta. Res. Bull.*, 287, 1938.

body weight. Feather *number*, however, increases less rapidly than surface area with increasing body weight. Feather *weight* increases with the first power of body weight, while feather *number* increases approximately with the 0.2 power of body weight.

The physiologic (thermoregulatory) significance of the above results will remain uncertain until a "physiologic unit" of wool or feathers is discovered. The fact that feather *number* and feather *weight* increase at such widely different relative rates suggests that probably neither is a satisfactory index of insulating or thermoregulatory capacity of feathers, and that a mechanical necessity not related to thermoregulation enters the observed relationships. Thus the weight of the supporting quill must, for mechanical reasons, increase more rapidly than that of the insulating vanes.

17.10: Summary. It is shown that to maintain homeostasis the body must change in form during growth, that is, with increasing weight. This chapter is not concerned with the detailed mechanisms of this change, but with the numerical interrelations between visceral organs, functional level and body weight, and linear size and body weight. The form of an animal at any time is the resultant of many factors, one of which is balance between geometric law on one hand and necessity for physiologic stability or homeostasis on the other.

Function is intimately correlated with structure and form. The art of animal judging is based on insight into these correlations; this art is crude because only the grosser aspects of form and structure are available for examination and comparison. The principle that function is an expression of structure is, however, unassailable. Thus a given level of milk production is an expression of certain structural details and organization, for example, structure and size of the mammary gland, cardio-respiratory system, digestive system, endocrine system, and so on. Likewise, the excellence of a work- or race-horse is the expression of the quality and size of its cardio-respiratory system, locomotory system, and so on. Similarly intellectual and emotional, or temperamental, characteristics are expressions of the relative quantity and structure of brain and nervous system, endocrine system, and no doubt of the more vegetative systems, such as cardio-respiratory, digestive, excretory, and so on. To quote Carrel⁴⁹, "Structure and function are two aspects of the same thing. Each structural detail possesses its functional expression. . . . The significance of a given structural state is bound to the knowledge of the corresponding physiological state. Structure and function must be considered simultaneously."

The parabola $Y = aX^b$ is the most satisfactory empirical⁵⁰ equation for relating part to part or to whole of structure or function in animals of different

⁴⁹Carrel, A., "The new cytology," *Science*, **73**, 298 (1931).

⁵⁰Cf. Teissier, G., *Ann. Physiol et physico-chim biol.*, **12**, 527 (1936), and *Travaux Station Roscoff*, **9**, 29-239 (1931).

size. The parabola is one of the three commonly employed equations in the physical sciences and engineering, and it is equally useful in biology. (The other two are the exponential, used for growth (Ch. 16), and the linear, which is included in the parabolic when $b = 1$.) The applicability of this equation to data means only that an increase of 1 per cent in X is associated with an increase of b per cent in Y . This is all it means. Thus, the equation relating basal metabolism, Y , to body weight, X (Ch. 13), by the equation $Y = 70.5X^{0.73}$ merely states that a body weight increase of 1 per cent is associated with a basal metabolism increase of 0.73 per cent; increasing body weight 100 per cent increases basal metabolism 73 per cent; or the ratio of $Y/X^{0.73} = 70.5$. While this equation is empirical, it is extremely useful because of its wide, clear-cut descriptive powers and its manipulative simplicity.

This parabola was employed successfully for relating many visceral organs to body weight. In most cases the value of the exponent, b , is less than unity, near 0.7 or 0.8. This is especially true for the metabolism-activating organs, that is, members of the neuro-endocrine system, and more particularly the brain, including the pituitary.

The weight of blood and heart have the highest value of b ; the blood and heart come nearest to varying directly with body weight in mature animals of different species. There are, however, considerable species differences in relative heart weight, depending on relative physical exertion. Athletic species have larger hearts than non-athletic, just as, usually, the more intelligent species have larger brains than the less intelligent. There are, of course, individual exceptions.

This parabola was also employed successfully for relating body weight to linear size in cattle, and the result used for estimating weight from chest girth and nutritive condition from height at withers. In this species, weight varies approximately with the third power of chest girth and with the fourth power of height at withers. Chest girth comes nearest to meeting the theoretical expectation that volume (weight) varies with the cube of linear size; chest girth is thus the best index of body weight. Height at withers is the best reference base for nutritive condition in cattle (and similar grazing animals), because in these animals height at withers, unlike chest girth, is relatively independent of environmental conditions. This is not the case for height growth in man, because most of the height growth is post-natal and also, unlike cattle, the post-natal human curve of growth in height has four apparently distinct segments, each having a different value of b ranging from 1.6 to 2.8.

Wool production increases with approximately the 0.5 power of body weight, as does surface area; that is, increasing body weight by 1 per cent increases wool weight in yearlings by about 0.5 per cent. The increase in

wool production is somewhat less at more advanced age. Feather *weight* increase more rapidly than feather *number*, less rapidly than surface area.

Beginning with puberty, linear growth follows the same course, that represented by the equation $Y = A - Be^{-kt}$ as weight growth; but the rate, k , of approach to mature size is different. Preceding puberty, when the rate of weight growth increases exponentially (at a constant *percentage* rate and at *increasing* time rate) the rate of linear growth is at a *constant time* rate. Each of the 21 different kinds of linearly measured complexes in cattle discussed in the text has a different growth constant, k , reflecting the age changes in form and, consequently, function. Growth after puberty, or after the major inflection, follows the same "ground plan" regardless of whether it be weight or linear size; preceding puberty, however, the patterns are different.

Several important "prediction" tables are presented and illustrated by charts.

17.11: Appendix. This appendix includes the tables which could not be included in the text because of overcrowding.

TABLE 17.1. THE RELATION OF ORGAN WEIGHT TO BODY WEIGHT IN APPROXIMATELY MATURE ANIMALS OF DIFFERENT SPECIES

(1) The constant b represents approximately (exactly for exceedingly small changes) the percentage change in organ weight corresponding to a 1% change in body weight. Thus, when the body weight increases from 850 to 950 pounds, which is a change of 11.76%, the intestines increase from 19.0 to 20.0 pounds, which is a change of 5.26%.

$$\text{Therefore, } b = \frac{5.26}{11.76} = .45.$$

(2) The constant S_b is the standard error of the slope b . For similar sets of data (204 cows of various breeds) the values of b could be expected two times out of three to differ from our values of b by not more than $\pm S_b$.

(3) The constant, ρ , the coefficient of correlation of the logarithms of the variables, indicates the degree of relationship between variables.

(4) & (5) The constants $+S_R$ and $-S_R$, called the standard error of estimate, indicate the percentage range about the fitted line that includes $\frac{1}{2}$ of the data. For example, the weight of intestines of similar 950-pound cows would not be expected more than one time in three to exceed 20 pounds by more than $.108 \times 20 = 2.16$ pounds, or fall below 20 pounds by more than $.097 \times 20 = 1.94$ pounds.

(6) The constant a is empirical, and unlike the other statistical constants depends on the units employed.

* Not significant.

*A, represents average; G, growing; M, mature. For example, in reference 22, one average of 52 mature males, and another average of 52 females were employed. In reference 24 twelve averages including a total of 120 growing animals were used.

† See the list of references to the literature in Table 17.6 (page 649).

Chapter 18

Aging in Relation to Growth and Efficiency with Special Reference to Milk and Egg Production*

Death is the end point in a long chain of events, and biologically it may be best understood in terms of the antecedent physico-chemical processes.
A. E. Cohn

Long life, the resultant of a sound, harmoniously functioning, slowly-aging body, is an obviously important factor in the long-range efficiency complex. Dairy cattle, for example, do not pay for themselves in milk and calves until they are about four years old, and the longer thereafter they maintain a satisfactory yield the greater the clear profit on the growth investment. The same holds true for many other productive processes, including those of man, who often requires 25-odd years of rearing and formal education for productive work and 25 years for proving himself. The phenomenon of aging is, therefore, of great agricultural and social importance as well as of personal and scientific interest.

The age at death is determined by two more or less interrelated sets of causes: (1) *external, i.e.*, from infections (scarlet fever, typhoid, tuberculosis, etc.), especially in the young, and (2) *internal, i.e.*, from the insidiously developing degenerative diseases (Fig. 18.10, after Pearl¹).

Many external causes of human death, particularly infections, are being brought under control by public health measures, by more efficient antisepsis, and by better personal hygiene, with the result that the *average* expectancy of life is increasing. Thus while in ancient Rome the average life expectancy at birth was 25 years, in contemporary (pre-war) Rome it is 55 years, and in contemporary continental United States it is about 64 years²; and the former major cause of death, infectious diseases such as tuberculosis, is giving place to non-infectious diseases, such as heart disease.³

* Grateful acknowledgements are made to Drs. E. J. Stieglitz, L. K. Frank, C. M. McCay and Ralph Bogart for critical reading of parts of this chapter; also to Dr. C. E. Marshall, Professor of Colloid Chemistry and to Dr. A. E. Stearn, Professor of Physical Chemistry at the University of Missouri.

¹ Pearl, R., and Raenkham, T., *Human Biology*, 4, 80 (1932).

² Rise in the mean life expectancy in the United States: 1800, 36 years; 1850, 40 years; 1900, 50 years; 1920, 55 years; 1930, 60 years; today, 64 years. In the 1920-40 period death rates from tuberculosis and pneumonia approximately halved; from circulatory disease approximately doubled.

³ Report to the National Resources Committee on The problem of a changing population, Government Printing Bureau, Washington, 1938.

Incidentally, the increase in average life expectancy increases the percentage of persons in the older age groups (Fig. 18.1a). In 1850, half of the population was adult, above 18 years; today about two-thirds of the population is over 18 years.¹ During the brief 1930-40 interval those of 65 years and above increased by 35 per cent, whereas the total population increased by only 7 per cent. The increase in the percentage of older persons, of course, raises interesting problems. Thus wisdom tends to be cumulative,

Fig. 18.1a. The influence of control of infectious disease on the age of distribution of the population. (Reproduced from negative 27324-A, Bureau Agricultural Economics, U. S. Dept. Agriculture.) The population under 20 years of age was over 50 per cent in 1870, 40 per cent in 1930, 35 per cent in 1940, and (it is estimated to be) 30 per cent in 1950, 25 per cent in 1980. The population between 20 and 60 years of age was 45 per cent in 1870, 53 per cent in 1930, and (it is estimated to be) 57 per cent in 1950, and 55 per cent in 1980. The chart was prepared from the following data (Report to the National Resources Committee, Government Printing Office, 1938):

Year	Population, Per cent				
	Under 5 yrs. of age	5-19 yrs.	20-44 yrs.	45-64 yrs.	Over 65 yrs.
1850	15.1	37.4	35.1	9.8	2.6
60	15.4	35.8	35.7	10.4	2.7
70	14.3	35.4	35.4	11.9	3.0
80	13.8	34.3	35.9	12.6	3.4
90	12.2	33.9	36.9	13.1	3.9
1900	12.1	32.3	37.8	13.7	4.1
10	11.6	30.4	39.1	14.6	4.3
20	11.0	29.8	38.4	16.1	4.7
30	9.3	29.5	38.3	17.5	5.4
35	8.5	28.2	38.6	18.8	5.9
40	8.3	26.4	38.8	20.2	6.3
50	7.9	23.1	39.7	21.4	7.9
60	7.1	22.2	37.4	23.3	10.0
70	6.7	20.6	35.0	25.9	11.8
80	6.4	19.6	33.7	25.9	14.4

to increase with increasing experience associated with the passing years, and from this viewpoint the longer the survival (prior to senile dementia) the greater the social gain on the initial rearing and education investment. History is replete with epochal contributions of men old in years and wisdom—Goethe, Michelangelo, Benjamin Franklin, Justice Holmes. Unfortunately, not only wisdom and generosity, but also folly, cruelty, maladjustment and invalidism tend to be cumulative. Similar young develop into different old, exerting different influences on society. Moreover, this rate of change differs. Some are mentally, emotionally, and in general physiologically old at 40 years; others are young at 80 years and wiser.

Fig. 18.1b. The first cycle represents the course of growth and senescence of a culture of lactic-acid producing bacteria in milk. Growth ceases after a characteristic concentration of lactic acid is attained. The proof that the accumulating acid is the limiting factor in growth is furnished by the fact that when the sour milk was neutralized with lime water, a second growth cycle was produced, virtually a duplicate of the first cycle. Similar curves result when food is a limiting factor. Cessation of growth leads to death of the bacteria.

Fig. 18.2. Age course of enzymatic activity in the human alimentary tract. Interpolated and recomputed in terms of percentage values and plotted from charts by Meyer, J., and Necheles, H., *J. Am. Med. Assn.*, **115**, 2050 (1940).

Returning to the causes of death, the controllable external causes of the chance variety need no explanation except insofar as accidents are more

Fig. 18.3a. Age course of reaction time to a simple electric shock in rats. From E. B. Brody, *J. Gen. Physiol.*, March 15 (1941). Note how the infantile reaction time recurs during senescence, but, of course, actuated by different factors.

Fig. 18.3b. Age changes in the cardio-respiratory reserve of man. Unpublished chart by H. H. Kibler, prepared from the numerous published papers by F. G. Benedict and associates.

likely to be fatal to the old because of reduced reserve power. Indeed, decline in the reserve power, or in the safety factors, required to withstand the stresses and strains of life is the best index of the aging process, and a theory of senescence should explain this decline.

The outstanding surveys of published literature⁴ and of projected studies⁵ on aging do not offer a general theory. Some maintain that aging is a cumulative expression of repeated environmental insults (infections, improper diet,

Fig. 18.4. Decline in the range of accommodation of the eye (presbyopia). "The change is due to the hardening of the lens by loss of water and the deposition of cholesterol and some insoluble globulins. . . . The early presbyopes die early, the late presbyopes die late."—Felix Bernstein, *Symposia on quantitative biology*, 2, 214 (1934). "The lens grows throughout life . . . the lens contains from birth to old age . . . embryonal parts . . . difference in relative proportion of young and old tissue within it." J. S. Friedenwald, in: "Problems of Ageing," p. 512.

toxic substances in the atmosphere, worry, etc.) which initiate and accelerate irreversible changes constituting senescence. It is agreed that external

causes condition the *average* expectancy of life at birth, but it is not agreed that such external causes condition the *individual* maximum life span. The life span of *Drosophila* was not increased, indeed it was reduced somewhat, by aseptic housing.⁶ Just as the maximum life span of man is about 100 years, so of *Drosophila* it is about 100 days and of the white rat about 1000 days. Each apparently grows and ages by its own hereditary clock (Ch. 19).

Senescence and death are, of course, not inherent in unicellular organisms, such as bacteria or yeasts; they simply divide continuously, provided, how-

Fig. 18.5. Age curves of basal metabolism, cardiac output, urea clearance, and blood urea concentration. Recomputed, equations fitted, and plotted from: *basal metabolism*, W. H. Lewis Jr., *Am. J. Physiol.*, **121**, 502 (1938); *cardiac output*, W. H. Lewis, Jr. *Id.*, p. 517; *urea clearance* (ability of kidney to remove urea from blood), and *blood urea concentration*, W. H. Lewis, Jr., and A. S. Alving, *Id.*, **123**, 500 (1938). As before, the exponents in the equations multiplied by 100 represent instantaneous percentage decline per year. These equations were fitted to the data by the method of least squares.

ever, that the metabolic products (as lactic acid, illustrated by Fig. 18.1b, or alcohol) are removed from and food supplied to the culture medium.⁷ But if growth stops, due either to accumulation of metabolic products or exhaustion of food, senescence processes set in and death follows.⁸

Likewise, many tissues from higher organisms are potentially immortal,

as demonstrated by the continuous growth of cancer tissue⁹ when transplanted to successive animal generations and by continuous growth of normal

Fig. 18.6. Age curves of basal heat production plotted on arithlog grids. Quadrants, II, III, and IV represent the daily metabolism, respectively, per unit surface area, per unit weight, and per individual, all plotted from data by Harris and Benedict, Carnegie Inst. of Washington, Pub. 279, pp. 123 and 118. Our numerical values of the exponents indicate that the metabolism declines at the approximate rate of 0.5 per cent per year; the exact value depends on the reference bases. We assume that the metabolism curves are exponential, declining at a constant *percentage* rate; Harris and Benedict assumed that the metabolism curves are linear, declining at a constant *absolute* rate (decline by 7.15 Cal. per year for men and 2.29 Cal. per year for women). Quadrant I represents the metabolism "standards" of Harris and Benedict, and of Aub and Du Bois to which we fitted equations. (See E. F. Du Bois' book "Basal Metabolism in Health and Disease".)

tissues when transplanted at sufficiently frequent intervals into fresh culture media.¹⁰ One of the tissue cultures obtained by Carrel from the chick heart

in January, 1912, is still growing by the continuous-transplantation method, thus demonstrating that body cells are also potentially immortal. But in the

Fig. 18.7. Age course of metabolism per unit weight plotted on arithlog paper. Ages are in months, except for humans and elephants in years. The numbers on the curves refer to corresponding legends on the chart. The elephant, like the horse, was measured in a standing position. See Missouri Agr. Exp. Sta. Res. Bull., 176, 1932, for details about the data.

body, as part of a closed system, they age and die. How shall one explain the mortal nature of the closed system in the face of the immortality of the component cells?

Many years ago Minot¹¹ wrote dramatically on the meaning of senescence: that the percentage growth rate declines with age and that "retardation of growth is old age and its cessation is death". According to this theory, generally accepted in principle, the aging process begins with the onset of life and is, indeed, most rapid at the earliest ages. Pragmatically, however, the aging of a given function is said to begin when the peak is passed. Thus a prize fighter is said to be old at 30 because his fighting ability has passed its peak, and is on the decline; a Supreme Court justice may be young at 70 years because his judicial wisdom may then still be at its peak.

Fig. 18.8. The age course of metabolism per unit weight of the domestic fowl. For details see Missouri Agr. Exp. Sta. Res. Bull., 176.

18.1: Physicochemical theory of aging. But why does cessation of growth lead to death? The simplest explanation is that body colloids, such as tissues, undergo progressive aging in the manner of non-living colloids.¹² Bancroft's¹³ suggestion that sodium rhodanate (NaCNS ?) when taken "about a teaspoonful a week of a 10% solution" may "retard the aging of the colloids of the body" calls attention, in a highly over-simplified manner, to the colloidal theory of senescence. Many age changes in the body are such as might

be expected from the assumption that its colloids are setting. Thus progressive dehydration¹⁴ with consequent decrease in the degree of dispersion and in related physicochemical changes¹² in the tissues are similar to those occurring in other non-living colloids. Reduction in elasticity,¹⁵ surface energy, and chemical reactivity are equally marked in aging inorganic and in body colloids. The rates of virtually all metabolic processes (Figs. 18.1 to 18.8) decline with increasing age, as might be expected from progressive decline in

Fig. 18.9. Estimated duration of life of different species as function of the rate, k , of approach to mature weight. The longer the growth period (the smaller the value of k), usually the longer the life span.

physicochemical reactivity. The age curve of ionic interchange is in harmony with the colloidal aging theory.¹⁶ The aging of tissues is apparently

¹⁴ Moulton, C. R., *J. Biol. Chem.*, **57**, 79 (1923). McCay, C. M., in Cowdry, E. V.,⁴ pp. 592-617. Murray, H. A., Jr., *J. Gen. Physiol.*, **9**, 789 (1926). Murray, J. A., *J. Agr. Sci.*, **12**, 103 (1922). H. S. Simms and A. Stolman, *Science*, **86**, 269 (1937), reported that tissue from persons over 70 years contained more water, chloride, total base, sodium, and calcium and less potassium, magnesium, and ash than from persons 30 to 40 years old.

accelerated by increasing temperature ¹⁷ in the same manner as the aging of inorganic colloids.

Dhar¹² suggested that death "from old age" in homeotherms occurs when the oxidation or metabolic rate falls below a certain level required for homeothermy. Figs. 18.5 to 18.8 (and data on pp. 707-9) on the decline in metabolic rate with increasing age may be illustrated by the following numerical data,

Fig. 18.10. Age trends in percentage mortality due to breaking down of (A) organ systems normally in direct contact with the external environment (plus external causes except suicide); and (B) organ systems normally not in direct contact with the external environment (plus "senility"). Chart by Pearl, R., and Raenkhram, T., "Constitutional factors in mortality at advanced ages." *Human Biology*, 4, 115, (1932).

obtained nearly a half century ago by Magnus-Levy¹⁸ on the metabolism of different individuals at different ages but of the same size.

Age	Body weight (kg)	Metabolism (O ₂ /min.)
15	44	217
24	43	196
71	48	163

¹⁷ See Chapter 11, and Loeb, J., and Northrop, J. H., *Proc. Nat. Acad. Sci.*, 2, 456, (1916), and 3, 382 (1917); also *J. Biol. Chem.*, 32, 103 (1917).

¹⁸ Magnus-Levy, A., and Falk, E., *Arch. f. Anat. u. Physiol. Suppl. Bd.*, 315 (1899).

The latest contribution to the problem on the interrelation of metabolism and age is also by Magnus-Levy,¹⁹ made a half century after the first report.

The decline in total metabolism with increasing age is associated in part with declining body weight and in part with advancing age, as indicated by the decline in metabolism per unit area. The decline is small, but it does not take much of a metabolic decline to reduce the body temperature to an unsafe level in the old when the homeothermic reserves are at a low level.

Data on the metabolism of aging rats²⁰ likewise indicate a slight decline in metabolism with increasing age. It was previously noted (Ch. 6) that many disabilities associated with aging may be viewed as being due in large measure to declining ability of the

Fig. 18.11. The age course of senescence in man as measured by the time rate of healing of wounds at different ages, and in domestic fowls by the time rate of egg production, and by the duration of life in fibroblasts grown in blood serum of chickens of different ages. 100 k represents the percentage decline for the unit of time indicated on the age axis. d represents the time required for any value to decrease to half, thus the time rate of egg production is halved in 5.8 years.

circulatory system to supply oxygen to the tissues and of the declining ability of the tissues to utilize the oxygen. But what causes these declines? Perhaps the setting of the colloids of the circulatory system and of the tissues in general.

Senescence has been attributed to the declining functions of some limiting endocrine glands, such as the thyroid, adrenal, and gonad. The gonads are not in the class of senescence-limiting, since castrated animals live as long, probably longer, than normal. The thyroid, adrenal, and other glands may become relatively overactive as well as underactive with increasing age—a problem for medical treatment²¹. The colloidal-energetic theory of senescence offers the simplest and most reasonable explanation of many phenomena.

18.2: Control of aging. In farm animals in particular and herbivorous animals in general deterioration of teeth is often the limiting factor which leads to digestive disturbances, malnutrition and ultimately death. In other species, particularly in humans and in working animals, deterioration of the

Fig. 18.12. The specific mortality of the given population of man appears to increase with increasing age of the surviving population. Thus the percentage mortality due to pneumonia increases at the rate of 5 per cent per year; or the mortality is doubled in 13.9 years (d represents the time in years in which the mortality is doubled). The increases in percentage mortality due to different causes are different; but for all the given causes the increases take place at a constant percentage rate as indicated by the linear distribution of the data on the arithlog grid.

cardiovascular renal system is often the limiting factor and cause of death (Fig. 18.10). The adequacy of the internal environment is dependent on that of the cardiovascular-renal system.²² In the words of Pearl,¹ "if the upper limit of the human life span (as distinguished from the average duration of life) is to be materially extended beyond what it now is, it will be necessary

²² Cf. Carlson, A. J., "An unwritten chapter in the physiology of aging," *Sci. Monthly*, July 1939.

for man to acquire, by some means not yet clear, a circulatory system organically superior to the already extremely good one—taken at its best—that he now has". The second most serious cause of death with increasing

Fig. 18.13. The age course of specific mortality in a population of *Drosophila*. The specific mortality increases at an approximately constant percentage rate, namely 3.9 per cent per day. (The specific mortality is doubled in 17.8 days.)

Fig. 18.14. The rise and decline of vital (lung) capacity plotted on arithlog paper. Between 28 and 65 years the vital capacity appears to decrease at the rate of 0.7 per cent per year (a slightly greater value than that for the percentage decline of basal metabolism). If the line is drawn to include age 80 years, the decline is about 1 per cent per year.

age is deterioration of the organismic controls^{22a} as manifested by the overgrowth of certain cells leading to cancer.

The simplest way for increasing the longevity of farm animals is by selective mating of the long-lived individuals. The progeny of old parents should

^{22a} Little, C. C., *Jour. Am. Med. Assoc.*, 125, 93 (1944).

tend to be long-lived, and also hardy, because long survival normally reflects a hardy, harmoniously functioning constitution.²³ From the viewpoint of longevity and long-range efficiency the present tendency to overwork and to dispose of animals at early ages is thus unfortunate.

Fig. 18.15. The rise and decline of strength of grip with increasing age. The nature of the distribution of the data does not permit an evaluation of its constants from the present point of view.

Fig. 18.15a. "Originality" (number of inventions or discoveries) as function of age. From Thomas Midgley, Jr., presidential address, American Chemical Society, Sept. 1944, in *Chem. and Eng. News, Am. Chem. Soc.*, **22**, 1647 (1944). See also Lehman.⁶⁰

The question under consideration, however, is not to develop hereditary long-lived animals, but to control the rate of aging of existing animals. What are the non-genetic factors conditioning longevity?

If one accepts the colloidal theory of aging, control would consist in the first place of making sure of sound development of the tissues by proper nutrition and by avoiding injuries, such as rheumatic fever; and secondly of

²³ Pearl, R., "Duration of life as an index of constitutional fitness," *Poultry Sci.*, **3**, 1 (1923).

avoiding influences which tend to "set" the body colloids prematurely. In brief, "the art of prolonging life is not shortening it" (Max Rubner).

According to the colloidal theory of aging, any factor which accelerates the metabolic processes beyond a relatively low level should accelerate the rate of aging and shorten the life span. The causative factors may be as diverse as muscular work, overactive nervous or endocrine systems, environmental temperature (low for warm-blooded animals, high for cold-blooded), small body size associated with early maturation and high heat production per unit weight, excessively high nutritive level, and so on. The higher mean life span of many female homeotherms may be associated with their lower energy metabolism.²⁴ Rubner's energetic theory of longevity²⁵ thus becomes a corollary of the colloidal theory. The influence of metabolic rate on the aging rate

Fig. 18.16. The rise and decline of milk yield with increasing age as indicated by 7-day records from the Advanced Register of Holstein cows. The circles are observed values; the smooth curve represents the equation in the chart. The fit of the equation to the rising segment of the age curve of milk yield indicates that until the maximum, the milk yield follows the course represented by the growth equation 16.12.

and on life span should be somewhat similar to the influence of temperature on the aging rate of inorganic colloids.

Rubner has calculated²⁵ that the quantity of energy metabolized per kilogram body from maturity to death is nearly the same in warm-blooded animals, except man. This is illustrated by the following estimates:

Species	Body weight (kg.)	Length of life (years)	Calories expended during life time per kilo adult body weight
Horse.....	450	30	170,000
Cow.....	450	26	141,000
Dog.....	22	9	164,000
Cat.....	3	8	224,000
Guinea pig.....	0.6	6	260,000

Unlike the above species, which generate about 200,000 Calories per kilo during the life cycle, man was estimated to generate about 800,000 Calories

²⁴ Landauer, W., and A. B., *Am. Naturalist*, 65, 492 (1931).

²⁵ Rubner, M., "Das Problem der Lebensdauer und seine Beziehungen zum Wachstum und Ernährung," Berlin, 1908.

per kilo. This may be correlated with the relatively long growing period,²⁶ that is, with the delay in the cessation of growth, in man as illustrated in Fig. 16.7, also Figs. 19.4–19.6. It is obvious from the colloidal theory of growth

Fig. 18.17. The rise and decline in milk secretion with the advance of the period of lactation of three groups of Holstein cows. The upper curve represents average milk yields of 47 cows milked 4 times a day. The middle curve represents the average yields of 32 cows milked 3 times a day. The lower curve represents 40 cows milked two times a day. The data were compiled by C. W. Turner of this (Dairy) Department (cf. Turner et al., *J. Dairy Sci.*, 6, 527(1923)).

The rising segments are represented by the equation

$$W = A - Be^{-kt} \quad (1)$$

The declining segments by

$$W = Ce^{-k_2t} \quad (2)$$

W represents milk yield at time t after calving. A is the maximum milk yield. C is the theoretical yield at parturition obtained by extrapolating the declining segment to zero time. k is the (daily) fractional decline in the successive increases of milk yield for the rising segment. k_2 is the fractional decline in the time rate of milk secretion for the declining segments of the curves. The smooth curves represent a combination of equations (1) and (2), namely

$$W = Ce^{-k_2t} - De^{-k_3t} \quad (3)$$

The numerical values of C and k_2 are the same as in equation (2). k_3 is very roughly the difference between k_2 and k , D is not far from the value of B . See Fig. 18.25.

that the longer the delay in growth cessation the longer the maintenance of the freshness of the colloids. The mean persistence of a given tissue is cor-

²⁶ Lusk, G., "The Science of Nutrition," p. 571-2, 1928 ed.

related with its continuous renewal, its colloidal freshness. Survival is indeed, as Minot expressed it, dependent on continuance of growth. This would be expected to hold for animals of different species, as shown in Fig. 18.9, which indicates that the life span tends to be a multiple (about five times)²⁷ of the duration of the growth period, and also within the species, as will be discussed in connection with McCay's results. (In Fig. 18.9, k is the constant of equation (16.12), representing the rate of approach to the mature weight, A ; the higher the value of k the more rapid the approach to maturity, that is, the shorter the duration of the growth period.) The prob-

Fig. 18.18. Until age 7 years, body weight and milk yield follow the same course as demonstrated by the excellent agreement between the age curves for body weight and for milk yield (expressed in terms of butterfat yield). To avoid the confusion of separate axes for absolute values of weight and butterfat yield, the values were plotted in terms of percentages of the mature values. The numerical data for the weights and yields are given in Missouri Res. Bull. 96.

lem of the influence of rate of maturation on the life span is complicated by the body-size factor; the rapidly maturing species usually has the smaller body size and, therefore, the higher metabolism per unit weight.

for exercise following middle age.²⁸ Slonaker²⁹ reported that rats having access to revolving drums for *voluntary* exercise ran about 5500 miles during life and *lived about 30 months*; control rats which had no access to revolving drums *lived about 40 months*. This observation needs confirmation, especially on dogs and horses.

Fig. 18.21. A comparison of the declines in milk production in cows (curves 1, 2, 4, 5, 6) and goats (curves 7, 8, 9) plotted on arithlog paper. There is a break in some curves, due to pregnancy between 6 and 9 months in cows, and 6 to 7 months in goats. The curves preceding the break are indicated by A, and those following the break by B. The exponents multiplied by 100 represent the monthly percentage declines in milk production, which are seen to range (for segments A) from 5.5 to 17 per cent for cows, and from 6.8 per cent to 19.6 per cent for goats.

Human mortality data tend to substantiate the inference that hard muscular work is probably associated with early mortality. Thus, according to Dublin and Lotka,³⁰ unskilled manual workers have a mortality rate of 13

²⁸ Cf. Pearl, R., "The Biology of Death," Philadelphia, 1922. "The Rate of Living," New York, 1928. "Research proves that hard work does kill," *New York Times*, Sept. 7, 1924.

per 1000 as contrasted to almost half, 7 per 1000, for the professional and executive classes, who presumably do not work so hard physically. No doubt poorer nutrition and other factors of hygiene and perhaps even heredity may contribute to this striking mortality difference. This is indicated by the fact that agricultural laborers have a lower death rate (8) than unskilled city laborers (13), and that the rural life expectancy is 62 and 65 (for men and women, respectively) as contrasted to 57 and 61 for urban life expectancy.

Fig. 18.22. The rise and decline of "vitality" in man (U. S. Registration area) with increasing age as measured by the breakdown of the nervous system, and excretory system. The data are represented as percentages of the maximum values. See Fig. 18.12 for the mortality data.

18.2.2: Longevity and temperature. Increasing temperature increases the metabolic rates of cold-blooded animals (Ch. 11, Fig. 11.1) and therefore increases the rates of growth and of senescence. Hibernation states of various types³¹ decrease the metabolic rates and consequently prolong life. This accords with the

³¹ For prolonging life in lower animals by desiccation, see Conklin, E. G., "The size of organisms and of their constituent parts in relation to longevity, senescence and rejuvenescence," *Pop. Sci. Monthly*, **83**, 197 (1913).

colloidal theory. The metabolism of warm-blooded animals is oppositely affected by temperature below a certain optimal level: the lower the temperature the higher the metabolic rate (Figs. 11.1 and 11.11), and one would infer the more rapid the aging rate. This inference needs to be tested on warm-blooded animals by housing such animals as mice and rats at various temperatures.

18.2.3: Longevity and the neuro-endocrine complex. High excitability due to genetic,³² endocrine,³³ psychologic,³⁴ and other peculiarities may ac-

Fig. 18.23. The rise and decline of "vitality" with age in man (U. S. Registration Area) as measured by the reciprocals of death rate, due to pneumonia.

Fig. 18.24. The rise and decline of basal metabolism with increasing age in early life. (See chap. 14.)

celerate the aging rate by increased metabolic tempo directly and indirectly (as by action on the circulatory system). The neuro-endocrine complex may thus influence the longevity complex.

³³ Cf. Brown, W. T., and Gildea, E. F., *Am. J. Psychiat.*, **94**, 59 (1937). Sloan, E. P., "The Thyroid," Springfield, Ill., (C. C. Thomas), 1936. Dunbar, H. F., "Emotions and Bodily Changes," New York, 1935.

³⁴ Fulton, J. F., Editor, "The hypothalamus and autonomic function," Vol. 20, *Assn. Res. Nerv. and Mental Dis.*, Baltimore, 1939.

Uncontrollable emotional behavior is observed clinically³⁶ as a result of brain abnormalities, and experimentally³⁶ following brain injury. Excitability often follows fatigue, worry, intoxication, and related factors which weaken the normal integrative control of the cerebral cortex.

Acute emotions are characterized by tense feelings and restlessness which profoundly affect visceral and other activities. Certain nerve excitations (parasympathetic, vagi, sacral) result in the production of excessive amounts of acetylcholine, sympathin, and histamine, which affect the heart, intestine, blood vessels, and skin, with consequent disturbances of various types.

Crile³⁷ has written eloquently from his great surgical experience in war and peace on the importance of emotions on the brain, thyroid, adrenal, celiac ganglion and sympathetic system (adrenal-sympathetic system) as "energy controller", and the burden

Fig. 18.25. The course of milk production with the advance of the period of lactation. This chart supplements Fig. 18.17, and illustrates the fit of one equation for the declining course of milk production, another for the rising course. The two equations are combined into one in Fig. 18.17.

they place on the cardio-vascular system. According to Crile, animals living in cold environment which are good conductors of heat (such as ocean water, 27 times as good a heat conductor as air), developed in the course of evolution particularly large brains

³⁶ Cf. Cushing, H., "Intracranial tumors," Springfield (Thomas), 1933.

³⁶ Cannon, W. B., and Britton, S. W., *Am. J. Physiol.*, **72**, 283 (1925). Bulato, E., and Cannon, *Id.*, pp. 295, 313. (Removal of cortex from brain stem in cats led to development of violent emotional outbursts on the slightest provocation. There was lashing of tail, arching of trunk, clawing, biting, etc., accompanied by signs of vigorous sympathetic discharge as indicated by erection of hair, sweating of toe pads, dilation of pupils, increase in blood sugar up to five times normal.)

³⁷ Crile, George, "A neuro-endocrine formula for civilized man." *The Educational Record Supplement*, Jan. 1941, Am. Council Education, Washington, D. C.

and thyroids to keep the heat generation at a high level. A socially or psychologically overstimulating environment may produce a somewhat similar, but in this case pathological, syndrome. Thus exophthalmic goiter, characterized by enormously high energy and protein metabolism, is peculiar to civilized man. "The brain-thyroid axis is destroying many of our most brilliant men and women through a pathologic physiology of oxidation called exophthalmic goiter and also through neuro-circulatory asthenia, or 'soldier's heart'. The axis partner of the brain, the faithful heart, is reaching its ceiling of possibilities".³⁷

Some emotions are acute, such as those investigated especially by Cannon in relation to the sympathetico-adrenal system;³⁸ others are chronic or conditioned, such as those investigated by Pavlov.³⁹

Fig. 18.26. To illustrate the effect of gestation on the course of milk production with the advance of the period of lactation. The rectangles and numerals indicate the month at which the cows were bred. The earlier the breeding the greater the decline in milk production at the end of the year. Compare to Figs. 18.21, 18.27, and 18.30.

What was said about man is true of animals. Good animal husbandmen appreciate the importance of gentle treatment of their animals, and are aware of the unpleasant conditioned reflexes that may develop, especially in horses and dairy cattle.

The division of causes of death into external and internal is thus somewhat arbitrary. Internal causes, such as those due to the aging of the cardiovascular-renal system, are influenced by the endocrine and nervous activities, which in turn are influenced by psychosocial and other factors and indeed by the nature of the thoughts, which are partly under control. As years roll on, from birth to old age, the individual "is reacting to

³⁸ Cannon, W. B., "Bodily changes in pain, hunger, fear and rage," New York, 1929 and 1934. Cannon, "The wisdom of the body," New York, 1932. Cannon, "The James-Lange theory of emotion," *Am. J. Psychol.*, **39**, 106 (1927).

³⁹ Pavlov, I. P., "Conditioned reflexes," London, 1927.

social life . . . with feelings of emotions which . . . influence bodily functions and may give rise to functional impairment and eventually to structural damage. . . . Worry, anxiety, and unhappiness may accelerate functional decline and aggravate the impairments of later life⁴⁰. If just the feeling of being old can lead to a diminution of functional activities, is it possible to delay aging by continuing life activities and maintaining a feeling of competence for life?⁴¹

Some of these ideas need to be worked out quantitatively by controlled experiments on laboratory animals by subjecting them to various psychologic factors (as fright) and following the metabolic levels and longevity; also by investigating the influence of various levels of thyroxine administration and thyroidectomy on metabolic levels and longevity. Similar investigations suggest themselves on the adrenals (administration of adrenaline, cortin, irradiating the adrenals, etc.) and on parts of the nervous system.

Neuro-endocrine research in relation to aging is a virgin field. The thyroid is perhaps the only endocrine that has been at all investigated in this relation.⁴¹ Very little is known about its function in aging.⁴² The histology of the thyroid indicates both decrease and increase in activities with advancing age⁴³. Some characteristics of old age resemble those of hypothyroidism.⁴² The respiration rate of thyroid tissue declines with

Fig. 18.27. Another illustration of the influence of the stage of *gestation*, on the course of milk production with the advance of the period of lactation.

increasing age,⁴⁴ but a given dose of thyroxine or thyrotropic hormone has a greater metabolic effect on the old than young.⁴⁴ Dogliotti⁴⁵ believes that the activity of the thyroid often increases with increasing age, and Cowdry⁴⁶ noted that the thyroid in a

111-year woman was in excellent condition. There are many such scattered observations in the literature on the age behavior of endocrines which are difficult to interpret because of their widespread interrelations. The involution of the thyroid (hypothyroidism) during aging may be the result of the aging of the body as a whole, and there is no reason for a *priori* assumption that thyroid administration would retard the general involutional process. Data are needed on this problem.

18.2.4: Longevity and diet. Overweight certainly reduces the expectancy of life, both in rats⁴⁷ and in man.⁴⁸ One possible unfavorable factor is the

Fig. 18.28. Influence of age on the course of milk production with the advance of the period of lactation.

increased energy metabolism associated with overfeeding (Ch. 4) and with carrying the extra weight of the overfed individuals. Then, too, excessive fat offers mechanical obstruction to the functioning of the visceral organs and

⁴⁸ Dublin, I. I., and Lotka, A. J., "Length of life," New York, 1936.

to the free movement of the muscles in the conduct of the business of living, thus increasing the energy cost of their performances.

One of the possible dangers of overfeeding with certain foods is of a somewhat different nature, namely, deposition of lipoids, especially cholesterol, in the blood vessels, especially the coronary arteries, thereby reducing the rate of blood flow to the heart muscle, and often causing sudden death by a loosened lipid fragment⁴⁹ and by thrombosis.

Fig. 18.29. Official test cows are bred later, therefore, do not show the depressing effect of gestation as the non-test cows.

Fig. 18.30. Comparison of the course of milk production in farrow and gestating cows.

Overfeeding, especially on carbohydrates, is thought to hypertrophy the pancreatic islets with hyperinsulinism, establishing a vicious circle. The more food, the greater the hyperinsulinism, and the greater the hyperinsulinism, the greater craving for food, with resulting obesity. The hypertrophy of the islets is then followed by their degeneration and diabetes.⁵⁰

⁴⁹ Leary, Timothy, "Experimental arteriosclerosis in the rabbit compared with human (coronary) experimental atherosclerosis," *Arch. Path.*, 17, 453 (1934). Cowdry, E. V., Editor, "Arteriosclerosis," New York, 1933.

⁵⁰ Hess, W. N., *Anat. Rec.*, 57, Sup. p. 37 (1933). Brody, S., *Ann. Rev. Bioc.*, 4, 383 (1935).

The above discussion on deleterious effects of overfeeding was concerned with the energy aspects of overfeeding on calories. With the possible exception of excessive intake of vitamins A and D, there is, perhaps, no danger of overfeeding vitamins.⁵¹ There is certainly no danger from excessive vitamin intake from vitamin-rich *natural* mixed foods, and, normally, this is the form in which vitamins should be taken. Vitamin intake should, on the contrary, increase with increasing age to compensate for reduced absorption,⁵²

Fig. 18.31. Age course of milk production as percentage of the 2-3 year level. These are averages of different animals at different ages.

utilization and storage, and greater needs for detoxification (Ch. 6), and especially because of the declining oxygen supply to the tissues, which may be compensated in part by increasing the concentration of the oxidation enzymes (vitamins) in the body. The ideal diet for the aged should then be relatively

⁵¹ Molitor, H., *Fed. Proc.*, 1, 309 (1942).

⁵² Cf. Irving, J. T., and Richards, M. B., "Influence of age on vitamin A requirements," *Nature*, 144, 908 (1939). Kruse, H. D., *U. S. Public Health Reports*, 156, 1301 (1941).

poor in calories and liberal in vitamins and other supplementary foods (Sects. 20.5–20.6).

Sherman⁵³ reported favorable effects on longevity and growth of liberal supplements of vitamin A, riboflavin, calcium, and related factors found in milk, even when superimposed on an already good diet. Thus, rats fed for 8 generations on a diet of one-third whole milk powder and two-thirds whole wheat reproduced and grew better and also lived longer than rats fed on a diet of one-sixth whole milk powder and five-sixths whole wheat. This illustrates Sherman's "principle of the nutritional improvability of the normal".

Fig. 18.32. Age course of milk production as percentage of the maximum production.

McCay⁴⁷ and associates reported spectacular data on the influence of interrupting growth during certain age intervals, beginning shortly after weaning, on the life span, as illustrated by the following table.

Diet	Maximum life span, of rats (days)			
	Males	Increase	Females	Increase
Rapidly growing.....	896		985	
Retarded 300 days.....	1018	122	1183	198
" 500 ".....	1103	207	1078	93
" 700 ".....	1025	129	1320	335

⁵³ Sherman, H. C., Campbell, H. L., et al., "The influence of food upon longevity," *J. Nut.*, **2**, 415 (1930); **14**, 609 (1937); and **21**, 221 (1941). See also Sherman, et al., *J. Biol. Chem.*, **60**, 5 (1924); **126**, 381 (1938); **137**, 627 (1941); *Proc. Nat. Acad. Sci.*, **14**, 85 (1928); **25**, 16 (1939); **27**, 289 (1941); News Edition, *Am. Chem. Soc.*, **19**, 1081 (1941).

Both the rapid and retarded-growth groups received the same quantities of basal ration diet, rich in protein, vitamins, and minerals, but not sufficient in calories to permit normal growth. The rapid or normal-growth group, therefore, received a starch-sugar-fat supplement to permit the rapid growth.

The *rapid-growth* group is seen to have had rather long-lived individuals, 896 and 985 days for males and females, respectively. The life span might,

Fig. 18.33. Age course of milk production of cows not on test.

perhaps, have been greater if this group received the supplement in the form of the vitamin-rich basal ration instead of the special vitamin-poor starch-sugar-fat ration. The *retarded-growth* group attained phenomenal life spans of 1103 days for a male retarded 500 days and 1320 days for a female retarded 700 days.

These striking results suggest several somewhat conflicting thoughts. The renewed growth following the 700-day caloric starvation may be in the nature of a new growth cycle, analogous to the second growth cycle of lactic-

acid bacteria shown in Fig. 18.1b, which does not differ in length from the first growth cycle. One is tempted to say that for this female, which survived 1320 days, life began at 700 days! This thought is in harmony with the colloidal aging theory according to which the life span is correlated with the length of the growth period (Fig. 18.9). One wonders whether the renewal of growth in weight following the 700-day retardation was also accompanied by initiating of sex activity.⁵⁴

One is reminded in this connection of Hartman's amoeba, kept alive and youthful for four months by repeatedly cutting off part of the body which

Fig. 18.34. Progressive improvement of Register of Merit Jersey cattle in the United States.

continued regeneration; and of Child's planarian⁵⁵ (Fig. 18.20) which reverted to the immature form on starvation, then again to the mature form on refeeding; and of Carlson's or Child's remark that a period of fasting gives one a feeling of exhilaration during the refeeding period.

These results do not necessarily imply that growth retardation or periodic fasting are desirable practices; growth retardation and fasting may prolong the life of a few hardy individuals, but, perhaps, the number surviving such a

⁵⁴ Asdell, S. A., and Crowell, M. F., "Effect of retarded growth on sex activity," *J. Nut.*, 10, 13 (1935).

⁵⁵ Child, C. M., "Senescence and rejuvenation," Chicago, 1915.

regime under normal conditions is small. This thought may be presented by the following questions: (1) What would be the life span of the retarded-growth rats if they had been kept on this retarded-growth level until death? Did the initiation of the new growth cycle after the 500 or 700 days of caloric starvation prolong the mean and maximum life span, and if so by how much? (2) What were the specific mortalities (deaths per 100 living of the same age) at various ages—for 10-day intervals (comparable to the yearly mortality tables for man)—of (a) the rapid-growth and the retarded-growth rats? Perhaps only such exceptional animals as are able to survive the starvation period benefit in longevity by the starvation regime. (3) What would be the

Fig. 18.35. Age course of milk production of the same 292 Red Danish cows. This is the only curve representing the same animals. The milk production is plotted against successive 400-day lactation periods, not calendar years.

influence of changed environmental conditions on these survivorships (these animals were housed in air-conditioned rooms)?

From an evolutionary viewpoint one would not expect that severe growth retardation would benefit. Birth usually coincides with the beginning of the season of lush food supply (Ch. 8) favorable for rapid growth and fattening, in preparation for future rigors.

McCay's results are, of course, extremely interesting from the viewpoint of the colloidal theory of aging, individual and species differences in the power to resume growth after severe retardation⁵⁵ (Fig. 19.16), influence of environmental conditions on such survival, selective breeding of hardy stock, and related limiting problems in growth and senescence.

⁵⁵ See, for example, Osborne, T. B., and Mendel, L. B., "The resumption of growth after long continued failure to grow," *J. Biol. Chem.*, **23**, 439 (1915).

In summary, from the viewpoint of longevity, moderate rather than rapid growth, and in later life, a low-calorie, moderate-protein diet of good quality,

Fig. 18.36a. Age incidence of illness. "Based on records for 9000 families in 18 states visited periodically for 12 months, 1928-31." Replotted, for purpose of condensation, from charts by S. D. Collins in *Public Health Reports* for October 11, 1935, p. 1404. Incidence is in terms of annual cases per one hundred, that is in per cent per year. The curve on home accidents from R. H. Britten, J. Klebba, and D. E. Hailman, *Id.*, p. 2061, Nov. 8, (1940).

with liberal vitamins,⁵⁷ and minerals seems best. From the viewpoint of immediate gross efficiency of productive processes, however, such as from the viewpoint of milk, meat, or egg production, high feed consumption and rapid growth may be more desirable in order to save maintenance and other overhead expenses.

Fig. 18.37. Survivorship curves of dairy cattle, plotted from data by Cannon and Hansen, Iowa Agr. Exp. Sta. Bull., 1939. Some old cows now living: the Guernsey cow Vestview Violette, 164104, now 21 years of age, gave birth to 15 offspring, has a record of 16000 lb. milk or 655 lb. butterfat in a year; Mixer Golden Charm, 151351, 19 years, had 15 calves, record of 12000 lb. milk, 616 lb. butterfat (*Guernsey Breeder's J.*, p. 260, Feb. 15, (1942)).

18.3: Criteria of aging and the prime of life. It is difficult to deceive an experienced horse trader concerning the age of a horse. The same is true for other farm animals and indeed for humans. Skin, hair, eye, voice, the very movements of the body and of its parts bear witness to the passing of years, to chronological age. It is not, however, as easy to *measure quantitatively*

⁵⁷ For detailed reasons, for possible importance of increasing vitamin intake with increasing age see Ch. 6, especially the reference to Rhoads, C. P.; also Cramer, W., *Bull. New York Ac. Med.*, 17, 3 (1941), and *Jour. Am. Med. Assoc.*, 119, 309 (1942).

physiologic or anatomic aging as it is to measure early growth with balance and tape.

Each structure and function passes through a "prime-of-life" which joins the period of obvious growth with that of aging. Thus the *percentage growth* rate of the body as a whole is maximal or prime in the early embryonic period (Figs. 16.2, 16.17, 16.18); the *absolute growth* rate is maximal during puberty (Figs. 16.8, 16.13); the minimal specific mortality or maximal vitality (reciprocal of mortality) occurs shortly before puberty (Figs. 16.8, 18.22-3); the absolute size of the thymus (and other lymphatic tissue) occurs near puberty and rapidly declines thereafter; maximal muscular power in man occurs near age 20 years⁵⁸ (Figs. 18.14-15); maximum potential reproductive activity in man is near 20 years and declines thereafter,⁵⁹ and so on.

As previously noted, it is difficult to estimate the age of prime intellectual power because of the influence of many factors thereon. Lehman⁶⁰ estimated that the prime intellectual power in man occurs at age 30 years, but qualified this by reporting that a third of the important contributions in chemistry were made after age 40 years, a fifth after age 50 years; literary masterpieces usually appear after 45 years. However, there is always a lag between the conception of an idea and its execution on one hand and its public appearance on the other. (See also Fig. 18.15a.)

18.4: Quantitative analysis of aging data. The best quantitative measure of aging is decline in adjusting ability to emergencies (homeostasis, Ch. 10), and decline in the safety factors especially in cardio-respiratory reserve power (Sect. 24.5). The prize-fighter of 30 is likely to lose his championship to his 20-year-old rival because the reserve powers of a 30-year old are below those of a 20-year old. The greater the need for rapid adjustment (as in prize-fighting, rapid diving in airplane or submarine, undergoing violent bombardment, exposure in a life-boat in mid-ocean), the less successful the older individual (in comparison to that of a 20-year old), the more likely will he be to experience "black outs", confusional states, and many functional disorders, lumped together under the heading of "shock" and "nervous breakdown." This the Army knows, and the actual fighting in this violent, rapidly moving war is largely between youngsters.

It is rather difficult to obtain strictly quantitative data on age changes in reserve power (homeostasis), although there are likely to be such data following the war's end, as the various branches of the fighting force are working on methods for estimating such power in selectees for the services. In general, the older the individual the lower the stroke volume of the heart (completeness of emptying of the ventricle per heart beat), therefore, the higher the pulse rate for a given exertion and less efficient the circulatory process. Moreover, the older the individual the lower the ceiling for the pulse rate, so that under conditions of stress circulation cannot keep up with the needs in

⁵⁸ Lehman, H. C., "The most efficient years in sports," *Res. Quart. Am. Ass. Health and Physical Education* 9, 3 (1938).

the old as well as in the young. The young and old are equally comfortable—maintain equal homeostasis—at rest, but not above a certain work level. Fig. 18.3b shows the age decline in cardiac reserve power (see Ch. 24 for detailed discussion of this index of cardio-respiratory reserve).

Attempts have also been made to measure reserve power in experimental animals by the ability to withstand poisons⁶² and bleeding.⁶³ Sims⁶³ reported that 825-day-old rats died with 12 per cent less hemorrhage than 100-day old rats; or in terms of probabilities of death, these are 16 times as great in 825 as in 100-day old rats.

The prime of life is not a point but a zone, the width of which varies with the particular index of aging employed. Fig. 18.3a illustrates the age changes in reaction speed to an electric shock⁶⁴ in rats, dependent on the function of many integrative and conducting devices. Egg production in fowls is in its prime during the first year (Fig. 18.11), but milk production in dairy cattle is not attained until the seventh year (Fig. 18.16).

Our basic problem is to describe quantitatively, mathematically, the decline in (reserve and homeostatic) power to withstand unfavorable conditions.

It is, of course, clear that by the time an animal attains the upper limit of the species-life-span it has experienced many risks, some from the external environment (infections, etc.) and others "spontaneous" (as blood clots, erosions, etc.) which eliminated at various ages most of its fellow travellers on the life cruise. The probabilities of elimination of a given individual at a given age, on a given age curve of specific mortality depends, on at least three well-defined factors: (1) impact intensity of the injuring agent, (2) susceptibility or resistance of the individual to the injuring agent, and (3) induction period, that is, the time intervening between the initial injury and death. Thus production of fatal cancer by coal tar requires about a fourth of a lifetime (about six months in a mouse and fifteen years in man). Many, if not all, deaths associated with aging are thus terminal stages of "remote causal factors".⁶⁵ The same may be said of other cancer deaths—whether initiated by estrogens, methylcholanthrene or by the Bittner⁶⁶ factor.

Such general considerations and the fact that resistance or reserve power declines with increasing age to all injurious agencies suggests the idea that specific mortality is likely to follow an exponential course with increasing age,

⁶⁶ The following papers indicate that breast cancer in adult mice is probably associated with the infantile nursing of cancerous mothers. Incidentally, breast cancer is absent in dairy cattle but frequent in humans and mice. Bittner, J. J., "Mammary tumor incidence in mice," *Science*, **84**, 162 (1936). "Breast cancer and mother's milk," *J. Heredity*, **28**, 363 (1937); *Am. J. Cancer*, **36**, 44 (1939); *J. Nat. Cancer Inst.*, **1**, 155 (1940). "Possible methods of transmitting susceptibility to breast cancer in mice," *Am. J. Cancer*, **39**, 104 (1941). Andervont, H. H., and McEleney, W. J., "Influence of foster nursing on incidence of cancer in mice," *Public Health Repts.*, **54**, 1597 (1939) and *J. Nat. Cancer Inst.*, **1**, 147 (1940). Smith, J. L., "Growth," Edinburgh, 1932.

that is, after passing the "prime of life" when mortality is minimum. This we⁶⁷ found to be the case for the specific mortality of man as well as for the fruit fly *Drosophila*. In brief, it appears that aging may be represented quantitatively by the same exponential or mass-action, or compound interest, equation

$$Y_1 = Ae^{kt} \quad (18.1)$$

that we used for representing early growth (Ch. 16). If one prefers, the equation

$$Y_2 = Ae^{-kt} \quad (18.2)$$

may be employed to represent the course of "vitality". Y_1 represents specific mortality and Y_2 specific vitality, the reciprocal of mortality; k represents the instantaneous mortality (or vitality) rate per unit time and at age t . The "vitality equation" (18.2), in the exponent k is negative, is more convenient for representing the age course of decline in egg and milk production, and healing of wounds.

When plotted on an *arithmetic* grid the slope of the curve represented by equation (18.1) increases exponentially and that of the curve represented by equation (18.2) decreases exponentially; when plotted on an *arithlog* grid, the slope, k , is constant, rising linearly in equation (18.1) and declining linearly in equation (18.2). Let us analyze actual aging data with the aid of these equations.

18.4.1: Analyses of aging in the domestic fowl and in man. Three sets of data on aging are shown in Fig. 18.11: upper left, age changes in egg production in Leghorn fowls;⁶⁸ lower left, age changes in suitability of chicken serum as a nutrient medium for fibroblasts⁶⁹ *in vitro* cultures; right, age changes in the index of healing of wounds (cicatrization) in man.⁷⁰

Equation (18.2) fits all three sets of data satisfactorily. The values of k are given on the chart; they are 0.12, 0.18, and 0.03, meaning that the instantaneous declines of egg production, duration of life of fibroblasts in chicken serum, and healing of wounds in man are, respectively, 12, 18, and 3 per cent per year. The rate of aging of the domestic fowl as measured by the decline of the ability of its serum to support life in fibroblasts is 6 times ($= 0.18/0.03$) that of man, as measured by the rate of healing of wounds. Is the potential span of life of man six times that of fowl?

The fitted equation for the egg production curve, namely,

$$Y = 179.2e^{-0.12t}$$

⁶⁷ Brody, S., "The kinetics of senescence," *J. Gen. Physiol.*, **6**, 245 (1924); Univ. Mo. Agr. Exp. Sta. Res. Bull., 105, 1927; *Growth*, **1**, 60 (1937).

⁶⁸ Brody, S., Henderson, E. W., and Kempster, H. L., "Senescence of the domestic fowl," *J. Gen. Physiol.*, **6**, 41 (1923).

⁶⁹ Carrel, A., and Ebeling, A. H., *J. Exp. Med.*, **34**, 399 (1921). Brody, S., *J. Gen. Physiol.*, **6**, 245 (1924).

⁷⁰ du Notty, P. L., *J. Exp. Med.*, **24**, 463 (1916). Brody, S., *J. Gen. Physiol.*, **6**, 245 (1924).

means that egg production begins at the *theoretically* maximum value of 179.2 eggs per year (that is, $Y = 179.2$ when $t = 0$), and since the decline in egg production is 12 per cent per year, the half value of A (179.2) is theoretically reached in 5.8 years; that is, $d = \frac{\ln 2}{k} = \frac{0.693}{0.12} = 5.8$ years (Sect. 16.3).

As previously noted, the age course of specific mortality probably reflects decreasing reserve to meet certain exigencies, such as attacks of pneumonia organisms. Does specific mortality follow an age course similar to that of healing of wounds? It should; and it does as illustrated in Fig. 18.12 for man and in Fig. 18.13 for *Drosophila*, plotted respectively from census data compiled by Dublin⁷¹ and from experimental results by Pearl and Parker.⁷²

The specific mortality data were plotted on arithlog grids. Their linear distribution means that the age course of specific mortality follows an exponential course, as represented by equation (18.1). As before, k represents the instantaneous increase per year for man, or per day for *Drosophila*, and d is the time in years or day, respectively, in which the mortality is doubled. Thus, the value of k for deaths from pneumonia is 0.05, meaning that the specific mortality or specific probability of dying from pneumonia increases at the instantaneous rate of 5 per cent per year, that is, it increases in geometric progression, and is doubled every 7.7 years. The value of k for specific mortality from pneumonia is seen to be higher than for healing of wounds. The value of k for *Drosophila* mortality is approximately 0.4, meaning that under the given conditions the mortality increases at the instantaneous rate of 4 per cent per day, or that it is doubled approximately every 18 days.

Equation (18.1) used⁴⁷ for representing the course of aging as measured by the increase in specific mortality was recently employed by Simms⁶³ for the same purpose and with similar results.

The value of k for mortality from infectious diseases (such as pneumonia) is of the order of 0.05; for cardiovascular-renal diseases it is more than double this value, 0.10-.12, which means that the prevalence of circulatory diseases increases very much more rapidly with increasing age. Death from pneumonia and similar infections occurs at all ages; but of circulatory diseases (except of the infectious rheumatic-fever type) rarely below age 40 years. It takes time for the setting of the circulatory system colloids and the clogging of the system with inert material. Likewise as regards the increase in cancer mortality, which has a value of k of 0.11, in the same class with circulatory diseases (Fig. 18.12), and the development of which involves a long induction period or a loss of organismic inhibitory control over cells which become cancerous. The increase in mortality from infection and cancer is perhaps secondary to or dependent on the decline in the circulatory system, which is the regulator of the internal environment.

18.4.2: Relation between growth and aging as measured by the course of milk production and similar processes. The larger size associated with growth enables an animal to produce more milk, or to produce larger eggs, or to accomplish more muscular work, but the animal also ages during the growth process; the growth process is also a senescence process. The life course of a function, such as of milk production or muscular work, is consequently of a rising and declining pattern. The rising segment reflects the increase in body size as well as of functions during growth; the declining, the aging process at constant body size.

⁷¹ Dublin, L. I., "Mortality statistics of insured wage earners and their families," New York, 1919. The data represent the general population experience of males, of the expanding United States Registration Area 1910-15. See also *U. S. Bureau of the Census, Special Reports*, 5, 303 (1936).

⁷² Pearl, R., and Parker, S. L., "Experimental studies on the duration of life," *Am. Nat.*, 55, 481 (1921).

Data are available on a number of age functions which illustrate the rising and declining pattern. Examples are vital capacity (Fig. 18.14) muscular strength (Fig. 18.15) and response to shock (Fig. 18.3a); but the most interesting agriculturally is the course of milk production, both for the life course (Fig. 18.16) and for the lactation period⁷³ (Figs. 18.17 and 18.25).

The rise in milk production up to seven or eight years in dairy cattle parallels in shape, although it lags in time, the rise in body weight. This is illustrated in Figs. 18.18 and 18.19. The age curve of milk production (up to 7 years) reflects the increase in size of the biological plant which produces the milk. Following age eight years, the decline in milk production reflects the aging process uncomplicated by increase in size in the milk-forming plant.

The life curve of milk production in Fig. 18.16 has this defect: the population has been rapidly decreasing with increasing age;⁷⁴ the comparison is thus made between the productive levels of animals that survive up to relatively advanced ages with others that do not survive so long. Other age curves suffer from similar defects. There is no doubt, however, that this curve illustrates the general quantitative relation between growth and senescence (Fig. 18.35 represents the age curves of the same individuals).

More spectacular in some respects than the life curve of lactation (Fig. 18.16) is the lactation-period curve of lactation, part of which is shown in Fig. 18.17. Here is an illustration of a cyclic, reversible, senescence process. Normally each year the mammary gland of dairy cattle comes to life functionally and, in many respects, structurally, and declines.

Not only the mammary gland but many other parts normally go through an annual rejuvenating and senescence process. During the lactation period the cow is in negative balance with respect to many substances. The losses are regained during the rest period.

The annual rejuvenation of the cow's mammary apparatus recalls a picture of Child's planarians (Fig. 18.20) which revert to the immature form on starvation. (See comments on McCay's retardation experiments.)

Returning to the aging of the lactation function, it appears that the decline in milk production following the attainment of the maximum yield at the prime of life or the prime of the lactation period is exponential, as indicated by equation (18.2). This is illustrated in Fig. 18.21, showing the decline in milk yield with the advance of the lactation period in a series of dairy cattle and dairy goats.⁷⁵ The lines represent the fit of equation (18.2) to the data.

The breaks in some curves with the resulting B segments reflect the fact that the animals were bred early in the lactation period and were performing a dual function, lactation and gestation. The difference between lines A extrapolated and B represents the depressing influence of gestation on lactation.

⁷³ Based on Missouri Res. Bull., 105 in which the history of this problem is presented in detail.

⁷⁴ See Missouri Res. Bull. 96 for the original data, and number of animals for each age. See Fig. 18.37 for the age course of survivors in dairy cattle populations.

⁷⁵ Brody, S., Mrs. Carl Sandburg and S. A. Asdell, Univ. Missouri Agr. Exp. Sta. Res. Bull., 291, 1938.

The values of the exponents represent the instantaneous declines in milk production per month. Thus the equation $Y = 45.3 e^{-.055t}$ represents the fact that milk yield declines at the instantaneous rate of 5.5 per cent per month; or what is the same, the instantaneous *persistence* of milk production is $100 - 5.5 = 94.5$ per cent per month—each month's yield is 94.5 per cent of the preceding month's yield.

Note that the value of the exponent, k , for curve 6 is 0.17 ; for curve 1, 0.053 . This means that the rate of aging of the lactation function in cow 6 is about three times that in cow 1. Obviously, these curves represent the aging of a special structure-function, not of the body as a whole, because cow 6 could not be aging three times as rapidly as cow 1. Different structures in the body age at different rates.

Fig. 18.21 represents the declining segment of the lactation curve. Fig. 18.17 represents the rising phase and its relation to the declining phase.

An interesting feature in Fig. 18.17 is that the rising segment of the curve resembles the segment of the growth curve following the major inflection (Ch. 16), and that it may be represented by the growth equation employed in Chapter 16 for representing that phase, namely (see Fig. 18.25)

$$Y = A - Be^{-kt} \quad (18.3)$$

This equation was combined with equation (18.2) to obtain

$$Y = Ce^{-k_1t} - De^{-k_2t} \quad (18.4)$$

Equation (18.4) has the *form* of the expression employed by physical chemists for representing simultaneous consecutive reactions of the first order, and no doubt simultaneous consecutive processes do take place. But in view of the complicated nature of lactation, it would be naive oversimplification to say that the processes are limited by two consecutive chemical reactions, although the concept of "master reaction" could permit one to say that the course of lactation may be limited by two relatively simple factors, one of which rises initially, representing the building up or growth phase, while the other declines, representing the aging or the senescence phase. We might interpret these age changes by referring to the changes in number and activity of the secreting cells and/or to changes in ovarian and pituitary activities. But for the present purposes it seems best to present the relationships between milk flow and time as frankly empirical equations in familiar *form*.

Equation form (18.4), representing the age course and the lactation-period course of milk production, may also be rationally employed for representing the age course of "vitality" defined by the reciprocal of specific mortality. The homeostatic mechanisms are weak during infancy and early childhood, attaining a maximum by puberty, then declining. One may, therefore, say that "vitality" increases during growth and declines during aging, as reflected by the reciprocal of specific mortality with increasing age. Figs. 18.22 and

18.23 reproduce our early attempt to fit equation (18.4) to the reciprocals of specific mortality data. Fig. 18.24 represents the fit of equation (18.4) to data on basal-metabolism per square meter of surface. Additional age curves for metabolism are given in Figs. 18.5 to 18.8.

Both growth and aging tend to follow an exponential course (Sect. 16.4). The central feature of an exponential course is constant *percentage change*. The change may be positive, exemplified by accumulation at compound interest; it may be negative, exemplified by depreciation at constant percentage. Some criteria of aging, such as decline in egg production, exemplify the constant-percentage depreciation concept [equation (18.2)]; others, *e.g.*, increase in specific mortality or early growth, exemplify the constant-percentage growth concept [equation (18.3)]; others, such as the increase in milk production in cattle from 2 to 7 years, exemplify cumulative increase at decreasing constant percentage rate, reflecting the later phase of growth; still others exemplify a summation of two types of change [equation (18.4) and Fig. 18.16 and 18.17].

18.5: Summary and appendix. A critical examination of the aging problem confirms Minot's generalization that aging is associated with cessation of growth, or rather decline in growth rate, since the body is in a dynamic state⁷⁶ and repair is a continuous process, so that the replacement type of growth continues until the end of life. Prolongation of the period of growth is thus likely to be associated with prolongation of the life span, with the prolongation of the mean persistence of a cell or tissue. This may explain the greater longevity of the late-maturing species and perhaps of some individuals within a species, as those of McCay's rats that survived a protracted period of retarded growth.

It is assumed that the body tissues, which are colloids, set and age in the general manner of inorganic colloids or of protein *in vitro*, although the details are different because of the dynamic nature of the tissue. According to this assumption, the rate of aging may be controlled, within limits, by prolonging the growth period, by avoiding high levels of metabolic activity and toxic influences, and by keeping the colloidal structure sound by proper diet. The extent of such control depends on the species. Some bacteria may be kept alive very long by low temperature (which depresses the metabolism). This method applies, within narrower temperature limits, to insects and other cold-blooded animals and to warm-blooded hibernators. Low temperature has the opposite, or metabolism-stimulating effect on warm-blooded, non-hibernating animals. The same is true of the prolongation of the growth period (that is, maintenance of new tissue). The life of a flat worm (planarian) was increased twenty-fold by compelling it to produce new tissue as result of periodic starvation and realimentation, and of an amoeba as result of periodic removal of a part of its body. The maximum life span of rats

⁷⁶ Schoenheimer, R., "Dynamic state of body constituents," 1942.

has been extended by growth retardation, by caloric (but not vitamin, mineral, or protein) undernutrition. These methods may not, however, be practical for prolonging the average life span because even caloric undernutrition reduces general vitality (in part by encroaching on the body protein which is used as fuel) so that only the few escaping death by the retardation process are benefited. The remedy may be worse, for most individuals, than the disease. This method is, of course, inapplicable to farm animals kept for high productive levels involving high metabolic rates.

Charts and mathematical equations, so-called "laws", are presented for the time relations of aging in man, fruit fly, fowl, and dairy cow. The central mathematical feature of the aging process following the prime of life is that it tends to be exponential; that mortality probabilities, for example, increase in a geometric ratio, according to the "mass law". Thus while the specific mortality in an adolescent human is about one in 800—a mortality rate which if continued through life would give a life expectancy of 600 years—the mortality rises (beginning with puberty) exponentially with increasing age at the rate of about 11 per cent per year for the degenerative diseases, such as vascular diseases and cancer, and at about 5 per cent for infectious diseases, so that the actual expectation of life is nearer 60 than 600 years.

A notable feature of *some* of these aging curves is that their slopes are, within limits, under control. Thus the average human life span has been rapidly increasing by better control of infections, diet, work and other conditions discussed in the text. Thus the mean life expectancy at birth in the United States was 36 years in 1800, 40 years in 1850, 50 years in 1900, 55 years in 1920, 60 years in 1930, and 64 years today. The average expectation of life at birth in Western Europe has increased from 20 years in the 16th century to 25 years in the 17th century, 32 years in the 18th century, 40 years in the 19th century, 49 years in 1900, 59 years in 1925, and near 62 years in 1938.

While, however, more people live to be old, the maximum life span has not been increased. Aging and death are the most certain characteristics of life, characteristics not without their advantages:

"In a world of great complexity, the attention of man is turned with relief to the more determinate limits of life. . . . The very definiteness of such points heightens the sense of reality. Death in particular is characterized by a finality which seems decisive. But death is only the end point in a long chain of events, and biologically it may be best understood in terms of the antecedent physicochemical processes."⁷⁷

The following numerical illustration of the equations and charts is presented for readers who feel more at home with original numerical values than with generalizing equations and curves.

The first table is a compilation of basal metabolism data at various ages obtained on "professors" and other persons well known to students of metabolism, and this table is, therefore, likely to have a personal interest to many readers beyond theoretical implications.

60-67	173/93	216/102	60	135/87	
65-69	186/86	222/112			

Illustration of the decline in egg production and in bird population with increasing age of domestic fowls, actual data. In the equations fitted to these data *Y* represents yearly egg productions (from Nov. 1 to Nov. 1) for age in years, *t*. Thus for the first equation the egg production began at the theoretical rate of 179 eggs and declined at the differential rate of 12% per year.

Age (years) Nov. 1 to Nov. 1	Light breeds ^{as} (S.C.W.L.)			Light breeds ^{as} (S.C.W.L.)			Heavy breeds ^{as} (B.P.R., R.I.R., & W.W.)			Av. of the same 450 S.C.W.L. birds	
	No. birds	Eggs per yr.	% of 1st yr.	No. birds	Eggs per yr.	% of 1st yr.	No. birds	Eggs per yr.	% of 1st yr.	Eggs per yr.	% of 1st yr.

	Y = 179e ^{-0.12}			Y = 193e ^{-0.14}						Y = 172e ^{-0.09}	

^{as} Hall, G. O., and Marble, D. R., *Poultry Sci.*, 10, 194 (1931).

Usually the higher the egg production during the first year the lower the life span, or the lowest first year production goes with longest life and highest life-time production, as indicated by the following data⁴⁶ on S.C.W.L. birds. The equation relating egg production, Y , with life span, t , is $Y = 179e^{0.024t}$

Egg production, first year.	169	160	158	156	152	145	142	141	118
Average life span, years..	3	4	5	6	7	8	9	10	11
Number birds surviving..	1867	957	450	232	152	80	48	23	5

The egg production in one group of fowls is given by the equation

$$E = 179e^{-0.12t}$$

which means that the egg production begins at a level of about 179 eggs per year, and declines at the instantaneous rate of about 12% per year. This equation may be employed for evaluating the potential or limiting number of eggs a fowl can produce by integrating the equation between age one-half year when egg laying begins and infinity:

$$E = \int_{\frac{1}{2}}^{\infty} A e^{-kt} dt = \frac{A}{k} [e^{-kt}]_{\frac{1}{2}}^{\infty} = \frac{179}{0.12} e^{-\frac{0.12}{2}} = 1370$$

It thus seems that if egg laying were to continue indefinitely, the total number of eggs laid by the average fowl of the group would be 1370, less than the number of oocytes in the fowl. It, therefore, appears that it is not the number of oocytes in the hen that limits the course of egg production, but the aging of some limiting organ or organs.

Similarly the limiting value for milk production during the declining phase of a lactation cycle is given by integration of the equation:

$$Y = A e^{-kt}$$

Integrating between zero and infinity, yields the ratio $\frac{A}{k}$, in which A is the initial level of milk production, and k is the differential decline of production per month. In case of the farrow group of cows in Fig. 18.21, $k = 0.055$; $A = 1170$ pounds milk per month. Hence, the limiting milk yield for a lactation period is $\frac{1170}{0.055} = 21,300$ pounds, which is a little over twice the milk yield for the first year, about 10,000 pounds.

The above train of reasoning was used for deducting⁴⁶ several important relations, for example the ratio of milk yield during a lactation period to the initial lactation level, A , and to the decline in productivity, k , with the advancing period of lactation.

Because of the voluminous body of data on milk yield (of the 25.5 million dairy cows in the U. S. A. the milk records of $\frac{1}{2}$ million per year are made publicly available by courtesy of the breed associations and Dairy Herd Improvement Associations) and enormous differences in the absolute level of production, it is customary to present the age-change data in terms of age changes in the factors required for converting the milk yield at any age to the mature equivalent at 6 to 8 years as indicated by the following values based on a recent compilation of Dairy Herd Improvement Association data by the U.S.D.A., B.D.I., and State Agr. Exp. Stations.

Age at freshening, yr...	2-	2½-	3-	3½-	4-	4½-	5-	6-	7-	8-
Factor for converting to mature equivalent.....	1.29	1.21	1.15	1.10	1.06	1.04	1.01	1.00	1.00	1.02

Age of freshening, yr..	9-	10-	11-	12-	13-	14-	15-	16-
Factor for converting to mature equivalent....	1.03	1.05	1.08	1.10	1.12	1.15	1.17	1.20

In other words, a 2-year animal produces about 29% below that of a mature (6 to 8 years) animal. Actually, individuals differ in their rate of change with age, and conditions of management (feed supply, frequency of milking, etc.) influence these values enormously (Figs. 18.31 to 18.35). Many tables on milk production as functions of age and of stage of lactation are given in Missouri Res. Bulletin 96.

⁴⁶ Univ. Mo. Agr. Exp. Sta. Res. Bull., 105, pp. 48-51.

Chapter 19

Physiologic Time and Equivalence of Age

For a being to exist is to change. *Henri Bergson*¹ (philosopher)

True age depends on progressive changes of the tissues . . . some remain young for many years . . . others wear out early in life. *Alexis Carrel*² (physiologist)

What am I to be tonight—90 or 40? Time is merely an accommodation to me. *Ethel Barrymore* (actress)

19.1: Physical versus physiological clocks. Physical time is measured by clocks in the manner that space is measured by rods. Both are empirical or arbitrary: the meter is the distance between two marks on a standard platinum-iridium bar; the day is the time taken by the hand of a standard clock to move a given distance on its dial. The meter is supposed to represent a certain distance on the earth; the clock mechanism is adjusted so that its hands match the rate of diurnal motion of the earth around its axis. Time is thus not a "cause" of change, but a frame of reference for change. Time does not change us but we change in time. "Time is the stream I go fishing in" (H. D. Thoreau).

Physical time, measured by the rotation of the earth around its axis, is assumed to flow uniformly just as the standard meter stick is assumed to maintain a constant length. There is no satisfactory method for checking these assumptions.

Physiologic time, measured by the rate of change in the organism, is, on the contrary, variable. If the life span is 90 days in *Drosophila* and 90 years in *Homo*, we may say that the physiologic clock of the fly runs about 365 times as rapidly as that of man. Similarly, different individuals of the same species and different tissues in the same individual change at different rates, that is, have different physiologic time or age scales. This concept is generally recognized as indicated by such expressions as³ dental age (age of appearance of

permanent teeth), anatomic age (age of ossification of the carpals and epiphyses), developmental age, mental age, pedagogic age, social age, and so on. Other indices of aging may be employed as age changes in the rates of: visual accommodation, chronaxy (response to nervous stimuli), oxygen consumption (metabolism), healing of wounds, growth of tissue *in vitro* in blood serum from different individuals, nutritional processes (digestion, assimilation, excretion), mortality (changes in ability to withstand a "dose" of an unfavorable condition ranging from an attack of "cold" to removal of a given

Fig. 19.1. An illustration of the use of several types of physiological ages (mental age, bone age, height age, developmental age, chronological age) for describing the growth of hypothyroid children, and of the influence of thyroid and of pituitary-extract administration on these ages. From L. Wilkins, W. Fleischmann, and W. Black, *J. Clinical Endocrinology*, 1, No. 1, p. 3 (1941) published by C. C. Thomas, Springfield, Illinois.

percentage of blood), milk production, egg production, muscular work, forgetting, learning, and so on.

The physiologic time scale changes with age, with the amount of "personal history" lived, or with the number of physiologic events packed in a day. To the rapidly changing child a year is a long time, to the "fossilized" adult, it is a short time. To quote Carrel:⁴

Child Development, 2, (1937), and 3, (1938). For social and developmental age as judged by play preferences, reaction to authority, etc., see R. A. Furley, *Educ. Res. Bull.*, 2, 1925, Catholic Educ. Press, Washington, D. C. For evaluation of aging in man after age 25 years see T. W. Todd, *Science*, 82, 181 (1935) (by the rarefactions in the skeleton observed by transillumination of the shoulder blades).

⁴Carrel², 1935.

Fig. 19.2. Growth-equivalence of Jersey cow (Eckles) and unmated female white rat (Donaldson). After age t^* , 1 month in the rat is equivalent to 11.9 months in the cow, and 1 gm. of weight in the rat is equivalent to 2.068 kilos in the cow. The period of growth preceeding the inflection is relatively longer in the rat than in the cow. (See Table 16.1 for values of k and t^* .)

Fig. 19.3. Growth-equivalence of cow (Eckles) and guinea pig (Wright). One month in the guinea pig is equivalent to 4.26 months in the cow and 1 gm. in the guinea pig is equivalent to 509.1 gm. in the cow. Unlike in the rat, growth in the guinea pig appears to follow the same course as growth in the cow from conception.

Fig. 19.4. Growth equivalence (following the major inflection) in man and sheep (of approximately the same mature weight, A). Man and sheep follow the same negatively exponential course following puberty, but the sheep is virtually devoid of the juvenile growth segment which is so characteristic of man. See also Fig. 16.7.

Fig. 19.5. Growth equivalence between man, white rat, and Jersey cow. The rat has a relatively somewhat longer juvenile and infantile period than the cow, and man has a very much longer juvenile period than either rat or cow. See Figs. 16.7 and 19.4.

Fig. 19.6. Equivalence curve for rat and man based on the assumption that the course of growth between conception and "maturity" (when body weight attains 98 per cent of the mature weight, A) is the same in the two species. This assumption is obviously not in harmony with the facts, and this method is, therefore, not applicable for estimating equivalence of physiological age between man and other species.

Fig. 19.7. Growth equivalence (following t^*) of Jersey cow and female white mouse. One month in the mouse is equivalent to 15.29 months in the cow. The segment preceding t is longer in the mouse than in the cow.

Fig. 19.8. Growth-equivalence for three breeds of dairy cattle plotted on the equivalent-time scale $k(t - t^*)$. C represents conception and B , birth. See Table 16.1 for the numerical values of k and t^* .

Fig. 19.9. Growth equivalence for male and female white mice plotted on the equivalent-time grid $k(t - t^*)$.

The content of a year in units of physiological time . . . is different for each period of an individual's life. . . . At the dawn of his life, man briskly runs . . . faster than the stream. . . . Toward midday, his pace slackens, the waters now glide as he walks. When night falls . . . man drops far behind. Then he stops . . . and the river continues on.

Anything which accelerates the rate of living accelerates the physiological-time clock so that, by comparison, the physical time clock appears to be retarded. Thus when body temperature is increased by fever, spontaneous⁵ or induced,⁶ time seems to pass more slowly because the body clock runs faster by comparison. The estimation of the flow of time (e.g., counting 60 at the rate believed to be 1 per second and recording the time by a stopwatch),

Fig. 19.10. This chart, showing the relation between the numerical value k and age at which a given fraction of the mature weight is reached, supplements Table 19.3. To illustrate the use of this chart, if the value of k is 2.3 (this is the value of k for the guinea pig), the chart shows that the animal reaches 99 per cent maturity (99 per cent A) at 22 months; 80 per cent A, at 9 months (from conception), and so on.

when plotted against body temperature, gives a slope in agreement with the van't Hoff-Arrhenius equation (Ch. 11).

Some drugs affect the psychological-time scale. Thus at a certain stage in marihuana intoxication one's notion of time undergoes a change. The flow of time "appears infinitely slow, owing to the number and variety of impressions which rapidly enter the mind, and, since time is measured only

by the memory of them, it seems infinitely long.”⁷ The distorted time scale in dreams offers similar illustration. The “relaxing” influence of alcohol may also be associated, in part, with a change in physiologic-time scale.

Changing environmental temperature changes the physiologic-time clock in cold-blooded animals in accordance with the van't Hoff-Arrhenius rule. The rates of feeding, growth, senescence, duration of life,⁸ and energy metabolism in insects and other cold-blooded animals vary with temperature in accordance with this rule (Fig. 11.1 and Sect. 11.3).

Fig. 19.11. Growth equivalence of cow and rat based on the assumption that the age when 98 per cent mature weight, A, is reached is equivalent in the two species (compare to Fig. 19.6).

Among the other possible controls of flow of physiologic time are thyroidectomy and thyroxine administration (Fig. 19.1), hypophysectomy, sickness, exercise, food supply (Figs. 19.16 to 19.20, and 16.30 to 16.38).

Different individuals and different organs of the same individual grow, mature, and age at different rates. Most biologic research (nutritional,

endocrinal, medical, agricultural) is indeed concerned, directly or indirectly, with the mechanisms of these rate differences, so engrossing personally, fascinating scientifically, and practical agriculturally. Our ability to control these rates of growth, senescence, and so on, must necessarily await our understanding of underlying mechanisms.

This discussion of relativity of physiologic time raises questions concerning methods for evaluating age equivalence, which we discuss next.

Fig. 19.15. Equivalence between human age curves of specific mortality due to different diseases.

19.2: Post-pubertal equivalence in weight growth.⁹ As previously explained (Sect. 16.5), following the major (pubertal) inflection, the growth velocity, dW/dt , declines at a constant relative rate, k , with respect to growth yet to be made, $A - w$, as indicated by the differential equation

$$dW/dt = k(A - W) \quad (16.9)$$

⁹ Brody, S., "Relativity of physiologic time," *Growth*, 1, 60 (1937). Brody, S., Sparrow, C. D., and Kibler, H. H., "Equivalence of age," *J. Gen. Physiol.*, 9, 285 (1926). Brody, S., Univ. Mo. Agr. Exp. Sta. Res. Bull., 102, 1927.

or by the integral equation

$$W = A - Be^{-kt} \quad (16.12)$$

or by the equation

$$W/A = 1 - e^{-k(t - t^*)} \quad (16.14)$$

in which W is the size or weight of the organism (or population) at age t ; t^* is the age at which the extrapolated post-pubertal curve cuts the age axis, A is mature weight; $(t - t^*)$ is, of course, age counted from t^* , and W/A is the fraction of mature weight attained at the age t (Ch. 16).

Fig. 19.16. The suppression and resumption of growth—that is of flow of growth time—in one rat by dietary manipulation, with a comparison to normally-fed rats. The charts were prepared from data furnished by Dr. T. B. Osborne in 1928. See also Osborne, T. B., and Mendel, L. B., The suppression of growth and the capacity to grow. *J. Biol. Chem.*, **18**, 95, (1914). The resumption of growth after long continued failure to grow. *Id.*, **23**, 439 (1915).

These equations furnish a precise method for computing equivalent time changes if the changes are exponential.

The speed of approach to the limiting or mature weight, A , is directly proportional to the numerical value of the relative growth rate, k , and the relative chronological durations of physiologically equivalent time intervals are, therefore, inversely proportional to the numerical values of the k 's. Thus from Table 16.1, the numerical value of $100k$ of the Jersey cow is 5.4 and of the female white rat, 64.4; one month in the rat is, therefore, physiologically equivalent to $1 \times \frac{64.4}{5.4} = 11.9$ months in the cow; or one month in the cow is physiologically equivalent to $1 \times \frac{5.4}{64.4} = 0.08$ month in the rat.

This does not mean, however, that a 1-month rat is physiologically as old as an 11.9-months old cow, because the post-pubertal equivalence scales may differ from the pre-pubertal.

As a matter of fact, the former differ from the latter for the cow and rat (Fig. 19.2), but are the same for the cow and guinea pig (Fig. 19.3). The rat, but not the guinea pig, has a relatively longer pre-pubertal growth seg-

Fig. 19.17. The influence of the nature of the food supply on the relative flow of growth age in rats. While the mature weight was approached at the same rate in Hoskin's and in Osborne and Mendel's rats, the mature weight of Hoskin's rats (fed ductless glands) was 230 grams, and Osborne and Mendel's 430 grams. Sherman's rats weighed 330 grams at maturity. Dr. Osborne furnished the original data for the Osborne-Mendel curves. See the bibliograph in Univ. Missouri Res. Bull. 96, for the original papers for the other data.

ment than the cow. Man has a pre-pubertal segment which is relatively still longer, so that if the age curves of man and other species are made to coincide post-pubertally they do not coincide pre-pubertally, as indicated by Figs 16.7, 19.4, 19.5, and 19.6.

This means that conception cannot be taken as a point of reference in preparing post-pubertal equivalence charts. Instead, we take for the point of reference the age, t^* , when the curve of equation (16.12) cuts the age

Fig. 19.20. Differences in rate of approach to mature weight of English children. Are these differences due to hereditary or environmental conditions? For the data see B. T. Baldwin, Univ. Iowa, *Studies in Child Welfare*, 1, No. 1, (1931).

Fig. 19.21. Relative approach to maturity of total body weight, calcium, and phosphorus in the rat. For the data see Sherman, H. C., and Quinn, E. J., The phosphorus content of the body. *J. Biol. Chem.*, 67, 667 (1926); Sherman and MacLeod, F. L., "The calcium content of the body." *Id.*, 64, 424 (1925). For more recent data see Caroline Sherman Lanford, H. L. Campbell, and H. C. Sherman, *J. Biol. Chem.*, 137, 627 (1941).

axis (explained and illustrated in Sect. 16.5; see especially Fig. 16.27, also Figs. 16.25 and 16.26). It is only after the age t^* that 1 month in the rat is

Fig. 19.22. Polish and Flemish rabbits approach mature weight at the same rate despite the great difference in mature weight of the two breeds of rabbits. From data by W. E. Castle.

Fig. 19.23. Suffolk and Shropshire-Merino sheep approach maturity at the same rate despite differences in mature weight.

equivalent to 11.9 months in the cow. (The numerical value of t^* may be read from the graph of the equation fitted to the data as shown in Figs. 16.27, 16.25, 16.28; t^* is the age when $A - W = A$, just as B is the value of A

— W when $t = 0$; or t^* may be computed algebraically as given by equations (13) to (15) in Chapter 16.)

Fig. 19.24. Ring dove and common pigeon reach mature weight in nearly the same time despite differences in mature weight.

Fig. 19.25. These Hampshire sheep require a longer time to reach mature weight than the other two breeds.

Fig. 19.26. Brahma fowls are much larger than Leghorn fowls, as shown in Fig. 16.49, and, unlike the Flemish and Polish rabbits (Fig. 19.22), Brahmas take much more time than Leghorns to attain mature weight. It is not, therefore, possible to generalize the relation between mature weight and time required to attain it.

Fig. 19.27 Substantiates the legend to Fig. 19.26 that body weight and time required to attain it are not closely related. As shown in Fig. 16.48, rat, dove, and pigeon are roughly in the same weight class. Yet pigeon and dove reach mature weight much earlier than rat partly because of the longer infantile-juvenile period in the rat and partly because the rate, k , of approach to mature weight, A , is more rapid in the pigeon and dove than in the rat. (See Table 16.1 for the numerical values of k and A .)

Fig. 19.28. Equivalence of age based on the proportionality of the mature weights, A , and rate of growth k , with t^* as null point.

Fig. 19.29. See legend for Fig. 19.28.

By way of illustration, let us prepare an equivalence chart for the rat and cow previously discussed, having the following constants:

	A (mature weight) (kg)	k	t^* (mos.)	
Jersey cow . . .	420.0	0.054	8.9	Age factor = $\frac{0.644}{0.054} = 11.9$
White rat . . .	0.203	0.644	2.03	

For the first pair of age-equivalence, t^* is taken; for the second pair one may take, for example, 8 months from conception in the rat, which is $8.0 - 2.03 = 5.97$ months from t^* . Now, 5.97 months in the rat is equivalent to $5.97 \times 11.9 = 71.1$ months from t^* , or $71.1 + 8.9$ months from conception, in the cow. 8 months in the rat and 80 months

Fig. 19.30. Equivalence of age based on plotting $\frac{W}{\Lambda}$ against the equivalent-time scale $k(t - t^*)$.

Fig. 19.31. See legend for Fig. 19.30.

Fig. 19.32. Equivalence of increase in population of man, *Drosophila*, and yeast plotted against the equivalent-time scale $k(t - t^*)$. Compare to Fig. 16.5.

Fig. 19.33. Equivalence of age with respect to growth in weight and growth in linearly-measured dimensions in Jersey cattle. No. 1 represents height at withers; No. 18, chest girth; No. 15 distance from a point on shoulder to ischium; No. 5 width of chest; No. 10 circumference of muzzle; No. 7 width of loin; No. 11 + 12 + 13 distance from horns to tail. See Fig. 17.11 for a graphic representation of these measurements.

in the cow, both counted from conception, thus constitute the second pair of growth-in-weight equivalent points. For weight equivalence, one reference point for both species is zero; the other, is the value of A , 420 kg for the cow and 0.203 kg for the rat. Having the reference points on the chart, the intermediate points are graduated uniformly and extrapolated if desired. The proof of the correctness of the above method is demonstrated by the good agreement between curves of widely different species in Figs. 19.2 to 19.5, and 19.7.

The method may be standardized for large-scale chart production by the use of equation (16.14). It states that for a given value of $k(t - t^*)$, there is one, and only one,

Fig. 19.34. Equivalence of age with respect to height at withers. No. 3 represents height at hip points; 6 width of hips; 9, width of forehead. For the other symbols see legends to the preceding chart.

value of W/A . If, therefore, values of W/A of different organisms are plotted against their corresponding $k(t - t^*)$ values, the resulting curves will necessarily coincide. After the data are plotted on the $k(t - t^*)$ grid, the absolute age scales are laid off, and the chart is completed. Equivalent ages for a given value of W/A may be read directly from the chart.

If the curves for two organisms are on different charts, the equivalence may be estimated with reference to the corresponding values of $k(t - t^*)$. Thus, assume that it is desired to estimate the age of the mouse corresponding to 92 months in the cow; from Fig. 19.8, 92 months in the cow corresponds to 5 on the $k(t - t^*)$ scale of the cow, and from Fig. 19.9, the value of 5 on the $k(t - t^*)$ scale in the mouse corresponds to 6.4 months. Hence 6.4 months in the mouse is equivalent to 92 months in the cow.

To facilitate plotting the curve of equation (16.14), Table 19.1 is presented in which W/A values are given for corresponding $k(t - t^*)$ values. In the preparation of these charts, coordinate paper was used having 20 squares between 0 and 100. The values in the column headed by $20 W/A$ are given for plotting on such paper.

Table 19.1 may also be employed for estimating the approximate equivalence of age for two organisms by reading the values of $k(t - t^*)$ corresponding to given values of W/A (right of the heavy line).

Instead of reading the equivalent growth ages of two or more animals from a chart, one may compute the ages, t , at which desired values of W/A are reached in animals under comparison as described below.

The growth equation

$$W = A - Be^{-kt}$$

may be rearranged to

$$A - W = Be^{-kt}$$

Then, taking natural logarithms on both sides,

$$\ln(A - W) = \ln B - kt$$

Solving for kt

$$kt = \ln B - \ln(A - W)$$

Then solving for age, t , we have

$$t = \frac{\ln B - \ln(A - W)}{k} \quad (16.12a)$$

which may be used directly for computing age, t , when any fraction of the mature weight is attained. By way of illustration, assume that it is desired to determine the age when

90 per cent of the mature weight is reached. The simplest procedure is to replace the W in equation (16.12a) by $0.9A$, obtaining

$$\begin{aligned} t &= \frac{\ln B - \ln (A - 0.9A)}{k} \\ &= \frac{\ln B - \ln 0.1A}{k} \end{aligned} \quad (16.12b)$$

from which evaluate t by substituting the numerical values for B , A , and k .

The above method for evaluating t for desired values of W/A is employed when one has growth equation (16.12) with its constant B . When one prefers growth equation (16.14), namely

$$W/A = 1 - e^{-k(t-t^*)} \quad (16.14)$$

the computation of t is carried out after rearranging to

$$\begin{aligned} 1 - W/A &= e^{-k(t-t^*)} \\ \ln (1 - W/A) &= -k(t - t^*) \\ t &= t^* - \frac{\ln (1 - W/A)}{k} \end{aligned} \quad (16.14a)$$

As before, t is the age when a given fraction of the mature weight, W/A , is attained. The value of t is computed, as before, by substitution. Thus if it is desired to compute t when half the mature weight is reached, W is replaced by $0.5A$, obtaining:

$$t = t^* - \frac{1}{k} \ln 0.5 = t^* + \frac{0.69315}{k}$$

The labor of looking up natural logarithms in equation (16.14a) may be saved by the use of Table 19.2, which gives the values of $\ln (1 - W/A)$ for different values of W/A .

Table 19.3, giving the ages (from conception) at which different percentages of the mature weight are reached, was computed with the aid of equations (16.12a) and (16.14a), and they agree very satisfactorily with the values obtained by interpolation from the smoothed weight-age curves of the original data.¹⁰

Finally, Fig. 19.10 furnishes another graphic method for estimating the age at which a given percentage of mature weight is attained, from the value of the growth constant, k .

Summarizing, following the major inflection, the age curves of different species coincide on plotting W/A against $k(t - t^*)$. Physiological equivalence of growth in size may thus be estimated graphically or algebraically as explained in the text. The computation of this type of equivalence was made possible by the fact that, following the major inflection, the time rate of growth declines, in all cases, exponentially (at a constant percentage rate), or the mature weight, A , is approached in all cases at a constant percentage rate, k (as indicated by the equation $W = A - Be^{-kt}$). Only the numerical values of k differ; the shape of the curve is in all cases the same.

19.3: Age equivalence based on the proportionality between two biologically equivalent points. Pearl and Doering¹¹ superimposed the mortality age curves of three species so that two biologically equivalent points coincide. The equivalent points chosen were (1) the ages at which the specific death rate is minimum; (2) when but one survivor is left out of 1000 starting at age of minimum specific mortality. Their result, reproduced in Fig. 19.12,

¹⁰ For the details of comparison see Brody, S., Univ. Mo. Agr. Exp. Sta. Res. Bull., 102, p. 17.

¹¹ Pearl, R., and Doering, C. R., *Science*, 57, 209 (1923). Pearl and Parker, S. L., *Am. Naturalist*, 58, 71 (1924).

shows that the paths travelled by the age curves of the three species are different; hence equivalence for the intermediate age intervals is not satisfactory.

Donaldson's¹² procedure of comparing age equivalence in man and rat on the assumption that 3 years in the rat is equivalent to 90 years in man is similar in principle to that of Pearl and subject to the same objection.

19.4: Pre-pubertal equivalence in weight growth. Preceding puberty the growth velocity, dW/dt , is proportional to (Sect. 16.4) the "effective weight",¹³ W' , so that the equation is

$$dW/dt = kW' = k(W + A) \quad (16.5a)$$

in which A is a constant. It may be interpreted to represent the weight equivalence of the growth impulse which, when added to the actual weight,

¹² Donaldson, H. H., "Boas Anniversary Volume," New York, 1906.

¹³ Weinbach, A. P., "The human growth curve," *Growth*, 5, pp. 230 and 231 (1941).

w , transforms it into the "effective weight", W' . The integrated form of this equation is¹³

$$W = Be^{kt} - A = Ae^{k(t-t^*)} - A \quad (16.5b)$$

which has the same form as equations (16.12) and (16.14). The equivalence for prepubertal age may, therefore, be determined in the same manner as the post-pubertal age. Weinbach has succeeded in preparing prepubertal-equivalence charts (Figs. 19.13a and 19.13b¹³).

Fig. 19.35. Shows that each measurement approaches mature weight in horses at a different rate. The linearly-measured complexes approach mature size more rapidly than weight.

19.5: Senescence equivalence. Age equivalence with respect to senescence data (Ch. 18, generalized by an exponential equation $Y = Ae^{kt}$ or $Y = Ae^{-kt}$) may be evaluated by the same method as weight growth, employing the equivalent-time scale $k(t - t^*)$, in which k is the relative rate of senescence, and t^* is the age when the index of senescence is minimum.

Thus if the age change in specific mortality (deaths per 100 living of the same age) is taken as measure of age changes in senescence, the method consists¹⁴ in plotting the ratios of specific mortality at age t to the minimum specific mortality, against the equivalence-time scale $k(t - t^*)$, in which t^* represents the age at minimum specific mortality, and k the relative increase in specific mortality per unit time, t , as explained in the preceding chapter. The results are shown in Figs. 19.14 and 19.15.

¹⁴ Brody, S., *Growth*, 1, 60 (1937), and Univ. Mo. Agr. Exp. Sta. Res. Bull., 105, 1927.

ferent organs in the same organism, at different ages, and under different conditions.

The rate of flow of physiologic time may be retarded or accelerated within certain limits. Thus in lower organisms, the flow of physiologic time may be practically stopped by desiccation.¹⁵ But "growth time" may also be practically stopped in mammals, as illustrated in Fig. 19.16. Such experimental stoppage of "flow of time" is ordinarily dangerous (few animals survive this ordeal), but it illustrates dramatically the concept of the rate of flow of physiologic time and its manipulation by nutritional means.

Figs. 16.31, 16.32, and 19.17, 19.18 exhibit growth curves of rats maturing at different rates—that is, growth time flowing at different rates—because of difference in the nature of food supply. Fig 19.20 illustrates the relative

Fig. 19.37. Equivalence of age and weight of typical Nordic and Asiatic race.

rates of approach to mature weight of British children under different social-economic conditions (see also Figs. 16.33, 16.34 and 16.50 to 16.54). Are these differences genetic, environmental, or both? What is the effect of growth rate (approach to mature weight) on senescence rate? Fig. 19.21 exhibits the relative rates of approach to maturity with respect to total body weight, calcium, and phosphorus. Fig. 19.1 illustrates the influence of thyroid on the rate of growth.

While all organisms are alike in the shape of the growth curve following the major inflection, there are species differences in the ratios of the length of the segment preceding the major inflection to that following it. The growth curve of man is distinguished by a particularly long juvenile growth segment (3 to 13–16 years), a segment which is virtually absent in the other species

¹⁵ Conklin, E. G., *Popular Science Monthly*, 83, 197 (1913).

examined (Figs. 16.6, 19.4, 19.5). This gives the growth curve of man a unique status with profound social, and especially educational, implications. Puberty in man occurs very late in the growth history, when about $\frac{2}{3}$ of the mature weight is achieved, whereas in the other species it occurs when about $\frac{1}{3}$ of the mature weight is reached (Fig. 16.6). One of the unique characteristics of the human family, the simultaneous presence of dependent children of different ages, is based on this relatively long pre-pubertal period. The mechanism, probably endocrine in nature, involved in this unique delay of puberty in man is one of great interest.

An important aspect from the growth-efficiency viewpoint is that animals differing in mature weight may reach maturity in the same time. Thus (Fig. 19.22), the Flemish rabbit is over twice as large as the Polish rabbit, yet both reach maturity in the same time. Obviously the gains in the larger rabbit are made more efficiently (and more profitably) than in the smaller. Likewise, rat, dove, and pigeon are in the same weight class (Fig. 16.48), yet pigeon and dove approach mature weight more rapidly than the rat (Figs. 16.48 and 19.24). What are the mechanisms controlling these peculiar differences in the rates of approach to mature weight?

Some of the technically useful features of this chapter are: methods of computing age equivalence in animals, plants, and populations; demonstrating similarities between the age curves of animals, plants, and populations; interpreting experimental results obtained on one species, such as rats or rabbits, in terms of other species, such as cattle or human beings, for physiologically equivalent age and time intervals.

Many equivalent charts are also presented in Chapter 16. See especially Figs. 16.6, comparing the age curves of growth of rat, yeast *population*, maize, oat, squash; 16.7, curves of man, cattle, swine, sheep, rabbit, fowls, rats, guinea pigs, pigeons; Figs. 16.35 to 16.38, equivalence of age for milk secretion in cattle; Figs. 16.30 and 16.32, remarkable differences in rate of approach to mature weight in rats. Additional equivalence charts, not discussed in the text, are presented because of their inherent interest and usefulness as references or standards for evaluating equivalence of growth age in different species and breeds of farm and laboratory animals.

The sources of data are indicated on the chart, the references are in the legends, or in Chapter 16; also in University of Missouri Agr. Exp. Sta. Res. Bull. 96.

Chapter 20

Nutritional Aspects in the Efficiency Complex

The scientist works in his laboratory with a few pink-eyed rats, and what he discovers is seen to be tied in with the deepest social and political and economic problems. *Gove Hambidge*

Tell me what you eat and I will tell you what you are. The destiny of a people depends on the nature of its diet. *A. Brillat-Savarin (1755-1826)*

20.1. Introduction: Species and individual differences in dependence on food for vitamins and amino acids. Every chapter in this book is concerned with some nutritional problem. This chapter considers several nutritional aspects as a whole, from the organismic viewpoint, with special reference to problems engaging students of practical nutrition of animals and man.

The nutrition of higher animals involves many nutrients, usually grouped into four broad categories: (1) protein or amino acid, (2) energy (which includes protein as well as carbohydrate and fat), (3) mineral or inorganic, (4) vitamin. There are, however, many species and even individual peculiarities with respect to the degree of dependence on food for each of the many nutrients included in these four categories.

For instance, most microorganisms, such as yeast, can synthesize amino acids and protein from simple compounds, such as asparagin, urea, succinamide, nitrites, nitrates, and ammonium bicarbonate. Higher animals, on the other hand, cannot synthesize what are called "nutritionally essential" amino acids. Yet ruminants, such as cattle and sheep, are not entirely dependent on their feed for the amino acids because one of their stomach chambers, the rumen or paunch, is virtually a fermentation vat with flourishing populations of microorganisms which convert simple non-amino-acid nitrogen compounds into amino acids for the synthesis of their body protein; these microorganismal-body proteins are in turn used as food by their host, the ruminant animal. It thus comes about that ruminants convert inferior proteins and even non-protein nitrogen compounds into superior proteins in milk and meat, which non-ruminants cannot do. Ruminants, especially dairy cattle, thus occupy a unique position in the efficiency complex in that they can convert feeds, with much crude roughage not useful to man and other species, and inferior protein or non-protein nitrogen compounds into the very best proteins, meat and milk. Swine and poultry may be efficient

converters of feed into meat or eggs, but the feed has to be concentrate rather than roughage, and the protein must contain all the essential amino acids and vitamins.

It is evident that the concept "biologic value" of protein (page 778), applicable to species with simple stomachs, such as rats¹, pigs², or chickens³, which are dependent exclusively on their diet for essential amino acids, is not applicable to ruminants⁴. Urea and casein, for example, when fed to ruminants as supplements to a low-protein ration yield virtually the same protein-utilization values. Results on the biologic value of protein obtained on rats or even rabbits are not, therefore, applicable to ruminants. Digestibility, not "biologic value" of the dietary protein is the major factor in evaluating protein for ruminants. It was formerly thought desirable to prepare complex grain mixes for dairy cattle on the assumption that the greater the variety the more likely is the mix to contain all the amino acids for synthesis of milk protein. This idea is now outmoded. It is now believed that one grain is as good as a mix of many⁵ if equally digestible and palatable (Fig. 20.4).

What was said about microbiological synthesis of essential amino acids in the rumen holds even more conclusively for microbiological synthesis of the B-complex vitamins (Ch. 6) in the rumen.

This has been demonstrated by *in vivo* (fistula) and *in vitro* (after slaughter) methods as well as by feeding experiments. Synthesis in the rumen was observed of thiamine, riboflavin, pyridoxine, nicotinic acid, biotin and pantothenic acid⁶. Ruminants, such as cattle, sheep, and goats, are thus not dependent on dietary water-soluble vitamins, nor on vitamin K. This fact is of immense national economic importance, permitting the production of the "almost perfect food", cow's milk, from feeds which are poor in protein and B-vitamins.

These statements about microbiological synthesis do not, of course, apply to calves prior to their development of the rumen function. In this condition they need dietary vitamins as do other species⁷.

Normally ruminants do not need dietary ascorbic acid. However, the rate of its synthesis seems to depend on the vitamin A intake⁷, age⁸, and general condition⁹. (The rate of ascorbic acid synthesis in non-ruminants also depends on thiamine supply⁹.)

Ruminants, of course, need dietary vitamin A, which they obtain in carotene form from green roughage.

⁹ Govier, W. M., *Science*, 96, 216 (1943).

The other species of farm animals do not have such "fermentation vats" in their stomachs, and the microorganisms in the intestine are relatively few and relatively useless for the purpose of synthesizing amino acids and vitamins. Moreover, the absorption from the lower part of the intestine is inefficient. The simpler the digestive tract the less the opportunity for synthesis of amino acids and vitamins by microorganisms and the greater the dependence on dietary nutrients, although, it is certain that, variable amounts of synthesis occur in all species^{9a}, even in humans⁷², which explains, in part, species and individual variations in sensitiveness to withholding dietary vitamins of the B complex. Biosynthesis has been demonstrated in the rat cecum^{10a}.

Anthropoids—including man—and guinea pigs are dependent not only for the B vitamins but also for ascorbic acid (vitamin C) in their food. The farm and laboratory animals investigated synthesize ascorbic acid (Ch. 6).

Ruminants, then, are least likely to develop nutritional deficiencies, being able to synthesize essential amino acids (within limits) and the B-complex vitamins and vitamin K. These are followed, as a rule, but with many exceptions, by the non-ruminant herbivores; then by omnivores, such as swine and poultry, which have still simpler digestive tracts, cannot consume much roughage, and which therefore frequently develop nutritional deficiencies under intensive commercial conditions of management. Grass, properly cured early-cut hay, and other young leafy greens are "protective foods," and the less their consumption the greater the chances for developing dietary deficiencies. Fourth, are such species as rats and dogs which do not normally consume appreciable quantities of greens and are, therefore, still more likely to develop nutritional deficiencies. The anthropoids, including man, come in the last category; they are, in a sense, the most exacting in their food needs because in addition to the vitamins needed by the other species, they are also dependent on their food for vitamin C and for unknown factors¹⁰.

It is, then, evident that in addition to the four broad categories of energy, nitrogen, minerals, and vitamins, which all animals must have, each species and even each individual has special dietary needs not necessarily applicable to other species and individuals. It is necessary to appreciate the lability of need in the same individual (with age and other conditions) and the differences between species and individuals in order to interpret apparently contradictory experimental results. Moreover, different species vary in their response to dietary situations. A dramatic example of this is furnished by the differences between the large fertile queen bee and her small infertile sister worker bee. This difference is developed by dietary means alone, by feeding "royal jelly" to the larva of the future queen but (following the third day) not to the future worker bee.

^{9a} Mitchell, H. K., Taylor, A., *et al.*, Univ. Texas. Pub. 4237, 1942.

^{10a} Guerrant, N. B., and Dutcher, R. A., *Proc. Soc. Exp. Biol. Med.*, 31, 796 (1934).

¹⁰ Walsman, H. A., *et al.*, "Nutritional needs of the monkey," *J. Nut.*, 26, 205, 361 (1943).

Nothing is known about the composition of "royal jelly" to indicate the nature of its growth and differentiating properties^{11a}. The worker bee is apparently not underfed or malnourished. The worker bee is not analogous, for example, to a vertebrate cretin produced by dietary iodine deficiency. The queen bee appears to be (qualitatively and quantitatively) superfed. It is doubtful whether such striking developmental differences can be achieved by superfeeding normally fed mammals and birds (Ch. 16). It may be that "royal jelly" contains not only what are usually called nutrients, but also hormones since, unlike the food of worker bees, it is a secretion and there is apparently no digestion in the queen bee to destroy hormones. If "royal jelly" contains hormones, its feeding may be analogous to injecting anterior pituitary growth hormones (Sect. 7.7).

Nutritional investigation includes many specialties, ranging from comparative nutritional psychology concerned with individual differences in food preferences to organic chemistry concerned with the identification and synthesis of nutrients; from sociology concerned with interrelation between diet and social and national welfare to physical chemistry concerned with the thermodynamics, time relations, catalysts, and other physico-chemical reactions constituting life. This chapter, naturally, makes no attempt to cover the field of nutrition but discusses several selected problems which seem germane to the spirit of this book. One of the problems, species and individual differences in dependence on food for vitamins and amino acids, and species differences in response to superfeeding, is discussed in this introductory section. The following section discusses species and individual differences in the use of what may be called "nutritional wisdom" in the choice of dietary components.

20.2. "Nutritional wisdom." It is fascinating to watch individual rats, chickens, children (and also the children's parents) making up their own ration, each to his unique taste, when a wide variety of foods is available *ad libitum* in cafeteria style. Individuals undoubtedly differ in food preferences; when followed, these preferences affect the individual's well being. This is illustrated, for example, by developmental differences of the animals described by Dove which were allowed to make their own ration.¹¹

If an animal chooses consistently a dietary pattern that leads to optimal growth, health, and longevity, then, conversely, the dietary pattern chosen by such an animal may indicate the proportions between the foods that lead to optimal growth, health, and longevity. Foods may this way, with the aid of superior assay animals, be arranged in a hierarchal order in terms of "palatability ratings." Palatability is an agriculturally important characteristic because the greater the palatability of a food the greater its consumption, the more rapid the productive process, the less the overhead maintenance cost, and the higher the economy per unit product (Ch. 1).

Dove¹¹ employed this method of self-selection for arranging foods by their palatability. When offered free choice of the following foods to rabbits between weaning and 11

^{11a} Pearson [Proc. Soc. Exp. Biol. Med., 48, 415 (1941)] reported that "royal jelly" is very rich in pantothenic acid.

¹¹ Dove, W. F., J. Heredity, 30, 157 (1939), and other references (ref. 17, Ch. 1).

¹² Dove, W. F., J. Nat., 25, 447 (1943); Human Biology, 15, 199 (1943).

weeks, they consumed 36 per cent whole-ground wheat, 21 per cent whole-ground yellow corn (mixed with 1 per cent cod liver oil), 18 per cent dried skim milk, 8 per cent whole-ground oats, 8 per cent alfalfa leaf meal, 3 per cent dehydrated fishmeal, 2.3 per cent meat meal, 1 per cent common salt, and 1 per cent bone meal.

Dove¹³ also observed that rabbits give highest preference to succulent foods with highest moisture and lowest fiber content. For instance, cabbage with the highest (96%) moisture and lowest (1%) fiber content in the succulent test foods was given highest preference, while white sweet clover before bloom with the lowest (75%) moisture and highest (6%) fiber content was given the lowest preference. Since high moisture and low fiber content are correlated with physiological immaturity and with the associated "tenderness" or high digestibility and high vitamin-mineral content, the rabbit's preference is essentially for the most digestible foods richest in vitamins and minerals, a preference that accords with "nutritional wisdom".

What was said concerning normal food choice often holds for "cravings" during certain nutritional disorders and under special stressful conditions. Such kinds and amounts of foods are generally sought as will restore and maintain a normal nutritional state. This accords with the principle of homeostasis (Ch. 10); and under natural conditions appetite for *natural* foods is an important guide to the nutritional needs of the body¹⁴. (Conditioned appetite for artificial foods or condiments, such as for sugar, patent flour, alcohol, etc., obviously belongs in a different category of wants.)

For instance, during a certain disease of the adrenal glands associated with extreme loss of common salt (Sect. 7.4), the animal automatically (under the influence of taste-hunger mechanisms) compensates the salt loss by developing an "abnormal" craving for and consuming enormous quantities of table salt¹⁴. Indeed, extreme salt consumption is often taken as a diagnostic symptom of such adrenal disease. Similarly¹⁵, removal of the parathyroids (which regulate calcium metabolism, see Sect. 7.5) is associated with a craving for and four-fold consumption of calcium; and conversely, unusual craving for bone or earth (in non-lactating and non-gestating animals) may indicate parathyroid abnormality. Another example relates to craving for unusual foods during pregnancy and lactation, as illustrated by bone consumption in herbivores (that do not normally consume animal products) during gestation and lactation when there is heavy demand for calcium¹⁶. There is also an increased need for protein, but not carbohydrate, during pregnancy, and pregnant rats fed by the self-selection method increase their protein, but not carbohydrate, intake¹⁷.

Some types of cravings associated with disease, such as sugar craving by diabetics, when satisfied, may aggravate the disease.

Carbohydrate and protein oxidation (catabolism) in normal manner is dependent on the presence of thiamine catalysts (Ch. 6); and interestingly enough the relative preference by rats for carbohydrate and fat depends on the relative supply of thiamine; its lack leads to aversion to carbohydrate and increased preference for fat and also for yeast (rich in thiamine); its abundance changes the preference from fat to that of carbohydrate¹⁸. This "nutritional wisdom" relating to thiamine does not, apparently, extend to riboflavin. Chickens¹⁹ and rats²⁰ do not differentiate satisfactorily between

riboflavin-poor and riboflavin-rich diets even if they suffer seriously from riboflavin deficiency.

Chicks balance their rations satisfactorily from natural feeds, as indicated by the following comparison at the Missouri Experiment Station²¹ between the free-choice (cafeteria) selection of chicks up to 8 weeks of age and the chick mash officially recommended by the Missouri Station.

Feed Consumption by Chicks During the First 8 Weeks After Hatching.

Feed	Free selection (%)	Recommended Missouri ration (%)
Cornmeal	39	50
Wheat shorts	29	15
Wheat bran	11	15
Dried buttermilk or	6	15
Dried skim milk	5	15
Meat scrap	5	0
Bone meal	3	4
Alfalfa leaf meal	1	0
Salt	0.2	1

The above self-selected ration contains about 18 per cent protein, 56 per cent carbohydrate, 4.7 per cent fat, 7.1 per cent ash, and 3.5 per cent crude fiber.

Commercially managed dairy cattle do not seem to be particularly endowed with nutritional wisdom²²; they tend to overeat, sometimes on one feed then on another, without apparent "reason".

If unconditioned weaning children²³ are given the opportunity to choose their food constituents, their choice is satisfactory. However, children are rarely unconditioned even before weaning and real free choice, in the sense of freedom from habit and suggestion, is perhaps impossible; therefore, conclusions from children's self-selective behavior are usually ambiguous.

Human choice of food is particularly confused by the more rapid advances in the technology of food processing than by the understanding of the nutritional significance of the processing. This lag of understanding behind technological skill leads to the development of irrational ideas and undesirable habits surprisingly difficult to eradicate when understanding does catch up with technology. A few examples with their social implications are cited in the following notes to illustrate this point.

Bread is the major food stuff, the common man's "staff of life". It is a good food if made from whole grain, as it contains good proteins, minerals, and vitamins. Until recently whole grain was used for bread making. But recently technology was developed for processing whole-wheat into "patent flour" which has very fine *culinary* qualities, making a "lovely crust" and a "big loaf" (per unit weight of flour). *Nu-*

²³ Davis, C. M., "Self-selection of diet by newly weaned infants", *Am. J. Dis. Child.*, 36, 651 (1926); 46, 743 (1933). Harris, L. J., *British Med. J.*, 2, 309, 367 (1933).

tritionally, however, the patent flour is very inferior to the whole-wheat flour because the milling process removes the nutritionally superior proteins and, roughly speaking, $\frac{1}{2}$ of the iron, $\frac{1}{2}$ of the calcium, $\frac{1}{2}$ of the copper, $\frac{1}{2}$ of the thiamine, $\frac{1}{2}$ of the riboflavin, $\frac{1}{2}$ of the choline, and nearly all the magnesium and manganese, leaving the patent flour a nutritionally impoverished product. The superior keeping quality of white flour is due mostly to these very nutritional deficiencies which make it an unfavorable diet for the pests (which thrive on the nutritionally superior whole-wheat flour).

The germ, middlings, shorts, red dog flour, and bran (Fig. 20.1) removed from the wheat in white flour manufacture²⁴, which carry the vitamins, superior proteins, and minerals, are fed mostly to cattle. But, as previously explained, cattle are independent of dietary B vitamins and essential amino acids, and they obtain minerals from the roughage and bone meal. We thus take away from the human dietary what man needs and feed to cattle what cattle do not need, which does not make particularly good "nu-

Fig. 20.1a and b. Wheat and corn grains. The wheat grain consists of about 1.5 per cent germ or embryo (which contains about 40 per cent of the whole-grain protein and 15 per cent of the vitamins), 15 per cent bran and inner coatings (which hold about 18 per cent of the whole-grain protein and 75 per cent of the B vitamins), 83 per cent endosperm (which contains about 11 per cent of the whole-grain protein and 10 per cent of the vitamins). Patent flour consists mostly of endosperm. Middlings or shorts is a mixture of some bran, some germ, and some red dog flour; red dog flour or white middlings consists chiefly of aleurone cells with some bran and flour particles. Middlings, the most nutritious part of the wheat, a very rich source of the vitamin B complex, is now fed to livestock.

tritional wisdom", or even horse sense. It has been said that white-flour products and sugar²⁵ furnish over half of the calories, but only 10 per cent of the vitamins and minerals. The milling also disturbs the supplementary balance between amino acid in the various parts of the grain²⁶, thus converting a naturally balanced protein combination into an unbalanced one.

Next to bread, milk is—or should be—the most important article of diet for the common man because it is the most efficiently produced, as above explained, and it is the

²⁴ For cereal chemistry consult the *Journal of Cereal Chemistry*; Stanford University Food Research Studies; Bailey, C. H., "Constituents of wheat and wheat products", Reinhold Pub. Corp., 1944; Sherman, H. C., "Modern Bread", Macmillan, 1942.

²⁵ Sugar, which, like alcohol, should be used as flavoring material and *apéritif*, has become a major article of the dietary. A century ago the per capita sugar consumption was 8 lbs per year; in 1941 it was 112 lbs per year (Sect-21.2).

²⁶ Chick, Harriette, *Lancet*, 1, 405 (1942). Murlin, J. R., et al., *J. Nut.*, 22, 573, 589 (1941).

least expensive protective food of animal origin (Ch. 21). Milk is rich in protein of the highest quality, minerals, vitamins, and the unique milk sugar. But after producing, about half of it is skimmed and the milk under the cream line is fed to farm livestock which convert the milk to other products (egg, meat, meat fat) at an overall efficiency of, perhaps, 10 per cent (Sect. 21.2). According to a recent report²⁷ "Less than half the available milk protein finds its way into the human diet. . . one can scarcely condone the lavish waste of nutritious materials now occurring annually in the dairy industry. The full significance of this incredible situation is appreciated when one realizes that the milk protein remaining on the farms each year is equivalent to the protein content of 20 million beef steers. . ." (Further analysis of the nutritional and social implications of processing wheat and milk, and the relation between the two, are presented in Sect. 21.2.)

This complex sequence of processing and reprocessing gives the impression that man is employing his ingenuity for devising complex methods for wasting food.

The "enrichment" of patent flour with vitamins does *not* compensate for the losses in milling, as indicated by short-time observations on dogs and rats on whole-grain and "enriched" white flour²⁸. The "enriched" bread is deficient in the amino acids lysine and valine, as well as in vitamins and minerals and unknown factors. Long-time experiment would, no doubt, bring out many other deficiencies. The Nutrition Committee of the National Health and Medical Research Council of Australia rejected the principle of bread "enrichment" with vitamin B complex²⁹, preferring to add cereal by-product, such as wheat germ, to the white flour or dried milk, and war-time, Britain compels the use of but lightly extracted "national wheat meal"³⁰.

Incidentally, oatmeal or rolled oats, nutritionally considered, is a whole grain rather than a milled one, like decorticated wheat, and is much richer in vitamins, minerals, protein, and fat than even whole wheat.

The least expensive, yet the best substitute for the losses incurred in milling wheat is non-fat milk solids added to the extent of 6 per cent of the white flour. Indeed, according to Mitchell³¹, who employed growth rate of immature rats as a measure of nutritional value of bread, skim-milk solid is a better supplement to white flour than the wheat residues discarded in milling, and such milk addition definitely improves the nutritive value both of "enriched" white bread and whole-wheat bread. The ideal, nutritionally complete bread would be made from whole wheat and whole milk. With the exception of ascorbic acid, a bread made from whole-wheat flour and whole milk would constitute a nutritionally complete diet (Sects. 21.2 and 18.2.4), although rather low in vitamin A.

White flour would also be greatly improved in nutritive value by supplementing it with such vitamin-rich and protein-rich foods as yeast, soybean flour, peanut flour, wheat germ, and so on. Aside from its nutritionally supplementary value, 3 to 10 per cent soybean flour mixed with white wheat flour makes an unusually attractive bread crust and holds moisture, thereby increasing the keeping quality of the bread.

The economically able who are also equipped with nutritional knowledge may, of course, compensate the white-flour deficiencies with appropriate protein-mineral-vitamin-rich foods—milk, eggs, meat, fresh vegetables, fruits. But most consumers lack both means and knowledge for correcting the white-flour deficiencies; hence the importance of an inexpensive "national loaf" which would supply the majority of consumers all the nutritional essentials (Sect. 21.2). The modern large-scale bakeries and

their cooperative institutes are in a position to experiment in blending various types of flours, milk solids, yeast, lecithin, agar, and so on, with the aim of developing both an attractive and nutritionally complete bread, and there is no doubt that they will live up to this opportunity.

What has been said about the losses in grain processing applies to other foods as well.

For instance, we have an abundance of efficiently produced inexpensive vegetable fats. The keeping qualities and decomposition temperatures of these fats (natural and hydrogenated) are approximately the same as of lard; yet lard has been produced on a large scale at an energetic efficiency below 10 per cent of that of vegetable fat and at a high nitrogen and mineral cost. There are good reasons for lard as for patent flour production, but the reasons are not from the overall national nutritional efficiency viewpoint (Ch. 1). This fact is becoming evident and efforts are already being made to develop a non-lard type of swine.

Some of the oil-bearing legumes, especially soybeans, are efficient protein as well as fat producers³¹, and the soybean promises to become a most important food crop in this country^{32, 33}.

Fish has approximately the same nutritional value for man as meat (except for iron), and it is said to be obtained by the fishing industry at a man-power cost of about one-tenth that of meat³⁴. But relatively little fish is used as human food in this country. After removing the oil, most of the commercial catch is used for animal feed or even fertilizer.

Yeast is one of the richest sources of the B-complex vitamins and protein of high biologic value, and the raw material for yeast manufacture (molasses, and more recently waste sulfite liquor) is plentiful. The nutritive value of yeast is quite close to that of lean meat of the same water content. Little yeast, however, is being used for human consumption. Attention is now given to yeast culture as human food^{35, 36}. Yeast, like soybean flour or milk, could be incorporated in bread up to, perhaps, 10 per cent, thereby enriching the bread with vitamins and proteins; or, like milk and soybean, yeast could be used for the preparation of very rich protein-mineral-vitamin soups to supplement the perverted white flour-sweets diet (Sect. 21.2).

While discussing yeast, a relatively new article in the human dietary, one may mention another new product with potentialities for supplementing the human dietary, namely dehydrated young cereal grass³⁷. Young-tender grass (harvested just before the jointing stage, about 3 weeks after seeding under favorable weather conditions) is rich in all essential nutrients and also in pectin and chlorophyll, which exert a hygienic effect on the digestive tract. Such grass constitutes a great reservoir of vitamins, proteins, and minerals. Grass, when young and tender, can be consumed in but limited amounts because of its laxative effect which, however, judging by the huge sale of laxatives, is also an advantage. Here is a problem in processing which may yield a matchless dietary constituent from a heretofore untapped resource (see page 780).

Fig. 20.2. The relation between monetary income, expenditures for food, and consumption of protective foods (re-arranged from Stiebeling¹⁷), indicating that malnutrition is a problem in dollars and cents as well as in proteins, vitamins, and minerals.

The waste, or failure to utilize, essential nutrients does not mean that there is an overabundance of them; nor do bulging granaries and cold-storage warehouses imply that we are well fed, for it takes money (Fig. 20.2), knowledge, and vision to obtain and utilize foods wisely³⁶. The following quotations, the first by a nutritional expert of the U. S. Department of Agriculture and the second by a nutritional expert of the U. S. Public Health Service and a member of the Nutrition Committee of the National Research Council, indicate the contrary.

"Millions of people in this country are living on diets that are below the safety line . . . a third or more of the families in the United States subsist on diets that should be classed as poor, . . . that take a toll in chronic fatigue, shifting aches and pains, certain kinds of digestive disturbances"³⁷.

"About 50 per cent of the children studied in Pennsylvania in 1939 were anemic"³⁸. In terms of adequate food for everyone, no food surplus has ever existed . . . the world has never had enough to eat. So-called over-production . . . is in reality failure to secure adequate distribution . . . Faulty food distribution is the most important contributory factor to malnutrition, and ignorance of the rules of good diet plus indifference to the consequences and bad dietary habits are the contributory underlying causes. Great Britain has shown that a national food policy based on nutritional adequacy can control malnutrition . . . In spite of poorer living conditions incident to war, the 1942 infant mortality in Britain was the lowest on record, and health has been maintained at a high level with a decreased general death rate and a negligible incidence of deficiency diseases . . . Such diverse problems are involved as the control of crop production, farm machinery, manpower, food distribution, transportation, food preservation and processing, storage and food preparation as well as education and diagnosis, prevention, and treatment of deficiency diseases"³⁹.

One is tempted to quote President Roosevelt's remarks on this subject³⁹ ". . . every survey of nutrition shows that there is in the United States undernourishment which is widespread and serious . . . We do not lack . . . the means of producing food in abundance and variety. Our task is to translate this abundance into reality for every American family"³⁹.

However, our ability to serve as the "bread basket of the world" or even to produce food in "abundance and variety" is doubted by many competent agriculturists, who feel that supplying food to furnish some 4000 Calories per day for each of the 135 million persons is itself a task of gigantic proportions which, unless the soil is carefully husbanded, threatens to turn much of our own "bread basket" into a "dust bowl" by over-cultivation. The report to the Food Advisory Committee, a Sub-committee on United States Food Allocation Policy, indicates that "the United States has never been and cannot become the food basket of the United Nations. U. S. food production, though impressive in itself, has never been more than a small fraction of total world production, and U. S. exports do not constitute more than a small percentage of the total food moving in world trade".

The social nutritionists ideal is an adequate diet for every member of society, at least for every child, since it is futile, for example, to furnish educational opportunities to

³⁹ Proc. National Nut. Conference for Defense, Federal Security Agency, U. S. Sup. Documents, 1942.

malnourished children who, because of their malnourishment cannot utilize these opportunities efficiently; and the same holds true for other members of the community. A corollary aim should be to acquaint every consumer with the simplest and most economical menus that would furnish all the nutrients in optimal proportions. The soybean makes a good base for such a menu, and is gaining rapidly in consumer favor. The U. S. Government has called for over a billion pounds of soybean meal to be converted into flour for human consumption in 1944, much of which, however, is intended for Europe. But in this country habituated to wheat and milk, a whole wheat-whole milk bread⁴⁰ in certain proportions (6 to 20 per cent milk solids in relation to flour) when supplemented with vitamin C, is virtually a complete food. (If defatted milk solids are used, the bread would also have to be supplemented with vitamin A.) Some day, maybe those who cannot afford to buy an adequate diet, at least children, will be furnished free such a whole wheat-whole milk bread, thereby avoiding irreparable malnutrition.

The following are two examples of simplified menus—which do not appear to the writer as simple—for adults suggested by the National Research Council (N.R.C. circular 115, 1943).

I	II
1 pint milk 1 egg 1 (or more) serving of meat or fish 1 (or more) potato 2 vegetables, one green or yellow 2 fruits, one citrus or tomato Cereal or bread, whole or "enriched" Other foods as desired	1 cup turnip greens 3 sweet potatoes 20 peanuts or 3 tablespoons of peanut butter 1½ oz. beans or peas 1 cup tomatoes 3 oz. cornmeal 3-4 oz. enriched flour ½ quart milk Small serving lean pork, 3-4 times per week Molasses, fat, etc. to complete meals

Whole wheat-whole milk bread and "other foods as desired" would be a much simpler and more practical menu.

The most conspicuous constructive wartime nutritional development is dehydration and compressing of foodstuffs, which may thus be preserved for long periods and transported long distances. "The weight of bombs dropped in the Ruhr in May as given in the daily press was 8,800 tons. This weight of dried milk would yield 4,000,000 pints of liquid milk a day for 31 days, about half a pint for every head of the population in a country the size of Belgium or Portugal"^{41a}. Compressed dry meat has about 30 per cent of the weight and 15 per cent of the volume of fresh meat; compressed dry egg has about 20 per cent of the weight and 10 per cent of the volume of fresh eggs; compressed dry milk has about 12.5 per cent of the weight and 10 per cent of the volume of fresh milk. The vitamin loss in milk is mostly in ascorbic acid (20 per cent loss in each drying and storage for about a year) and thiamine (about 10 per cent loss in drying and 20 per cent in storage). These developments promise to revolutionize the food-catering industry. Dry milk is already being sold (on an experimental scale) in some grocery stores (Sect. 21.2).

20.3. The *ad libitum* and paired-feeding methods for the nutritional evaluation of foods. The usual method for comparing the nutritional values of two rations, or some limiting nutrient (such as protein, vitamin, mineral) in the ration, is to feed them to two groups of immature test animals, for example, to litter-mate rats A and B of the same sex, weighing 50 to 80 g at the beginning of the trial. If, for example, rat A grows more rapidly than rat B, the ration fed to rat A is nutritionally superior to that fed to rat B. Here the growth rate of immature rats is taken as a measure of the nutritive values of the two rations.

This example is an obvious oversimplification. For instance, some rations not only accelerate growth but also accelerate senescence, which is not so good, and they may have unfavorable effects on other processes such as reproduction, lactation, egg production, muscular work, and so on.

Moreover, speaking from the energetic-efficiency viewpoint, two animals may gain weight at different rates, yet gain energy at the same rate. This is because some types of weight gains involve greater energy storage per unit live weight than others. For instance, one gram of protein gain is necessarily associated with three grams of water gain, whereas one gram of fat gain is not so associated with water gain. Moreover, the energy equivalent of one gram fat is $2\frac{1}{4}$ times that of one gram protein. Hence, one gram fat gain is calorically equivalent to about eight grams protein gain (including the associated water). Indeed, it has been demonstrated by one group of investigators⁴¹ that, despite differences in weight gain of rats fed the same amounts of food containing different percentages of protein, there was no difference in *energy* gain.

There is some disagreement, however, on the equality of energy gain on rats paired to the same dietary energy containing different protein percentages and inducing different growth rates⁴². For instance, the following data⁴² indicate that the pair-fed rats gained different amounts of energy. The differences between Hogan's and Forbes' results may be only apparent due to methodologic differences.

The Influence of Protein Percentage in Diet on Growth Rate and Energy Storage (after Forbes, *et al.*).

Dietary protein (%)	Weight gain (12 wks) (g)	Energy stored (12 wks) (Cal.)	Nitrogen stored (12 wks) (g)	Digestibility (%)		Maintenance heat (Cal.)
				Feed energy	Feed nitrogen	
10	79	217	2.51	91.5	88.1	1709
15	107	263	3.68	91.8	91.8	1668
20	119	296	4.08	92.9	93.3	1642
25	119	302	4.17	93.4	94.2	1626

⁴¹ Johnson, S. R., Hogan, A. G., and Ashworth, U. S., "The utilization of energy at different levels of protein intake", Univ. Missouri Agr. Exp. Sta. Res. Bull. 246 (1936).

⁴² Forbes, E. B., *et al.*, *J. Nut.*, 10, 461 (1935); 15, 285 (1938); 18, 47, 157 (1939); 20, 47 (1940); *Science*, 99, 476 (1944). Hamilton, T. S., *Id.*, 17, 583 (1939); 18, 565 (1939); Brody, S., *Ann. Rev. Bio.*, 4, 399 (1935).

Most important from the present viewpoint is that the ration offered to (the more rapidly growing) rat A may be more palatable or otherwise stimulate a higher food consumption, so that the higher growth rate of rat A may be due not to the superiority of its limiting nutrient as such but to the fact that it stimulates a greater food consumption.

One could, of course, partly overcome this confusing situation by expressing the growth rate in terms of weight gains per unit food consumed, such as by the efficiency equation we used (Ch. 1):

$$\text{Growth efficiency} = \frac{\text{weight gain (energy units)}}{\text{feed consumed (energy units)}} \quad (20.1)$$

Osborne and Mendel⁴³ defined the nutritive value of protein by a similar equation:

$$\text{Nutritive value of protein} = \frac{\text{weight gained}}{\text{protein consumed}} \quad (20.2)$$

and McCollum and associates⁴⁴ defined it by the relation:

$$\text{Nutritive value of protein} = \frac{\text{nitrogen retained in body}}{\text{nitrogen consumed}} \quad (20.3)$$

The objection to the above method for compensating for differences in food intake is that the animals consuming more food grow larger and have a correspondingly higher maintenance cost. Theoretically, the situation is confused by the maintenance factor.

Osborne and Mendel⁴⁵, therefore, suggested what is now called the "paired-feeding method" involving equalization in food intake in test animals. As indicated by the following table⁴⁵, the idea is to have the animals on the various diets under investigation consume equal amounts of food (438 g) in the same time (77 days). The relative weight gains are supposed to indicate the relative qualities of the protein under investigation. Thus in the following table, the rats are seen to gain 71 grams on the ration containing 8 per cent casein, 77 grams on the one containing 8 per cent lactalbumin, and so on.

Osborne and Mendel also used a combination of food equalization and body-weight equalization methods for comparing the growth-promoting

⁴³ Osborne, T. B., Mendel, L. B., and Ferry, E. L., "A method of expressing numerically the growth-promoting value of proteins", *J. Biol. Chem.*, **37**, 223 (1919). See also Osborne and Mendel, "The comparative nutritive value of certain proteins in growth, and the problem of the protein minimum", *J. Biol. Chem.*, **20**, 351 (1915). (Here weight gains were related to protein intake when the ratio weight gain per protein consumed is maximum. The different proteins were fed at 9 to 10 per cent levels for 9 weeks. The animals were fed *ad libitum* because of the belief that the rats consume food in proportion to caloric rather than protein needs.)

⁴⁴ McCollum, E. V., Orent-Keiles, E., and Day, H. G., "The newer knowledge of nutrition", Macmillan, pp. 126-27, 1939.

⁴⁵ Osborne, T. B., and Mendel, L. B., "A quantitative comparison of casein, lactalbumin, and edestin for growth or maintenance", *J. Biol. Chem.*, **26**, 1 (1916). This method was also used by Hopkins, F. G., *J. Physiol.*, **44**, 425 (1912).

properties of different proteins; they adjusted the various protein percentages so that all the assay animals made equal weight gains. The ideal condition for comparing biologic values was considered to be attained when animals of similar weight and age "eat the same amount of food in the same number of days and gain the same amount of weight, the protein factor being the only variable".

Relative Weight Gains of "Pair-fed" Rats in Relation to the Level and Nature of Dietary Proteins.

Protein	Protein in diet (%)	Food intake (g)	Length of trial (days)	Weight gain (g)
Lactalbumin	14.8	438	77	22
Lactalbumin	8.0	438	77	77
Edestin	8.0	438	77	50
Casein	8.0	438	77	71
Casein plus cystine	8.0	438	77	95
Casein	10.8	438	77	85
Casein	16.2	438	77	105

A great deal has been written for and against the "paired-feeding"⁴⁶ and "body-weight equalization"⁴⁷ methods for evaluating foods.

The distinctive feature of the paired-feeding method is that the food-energy intake of the assay animals on all rations is equalized to the level of the animal consuming the least food.

The advantage of the body-weight equalization method is that the maintenance cost is more likely to be the same for the animals on the diets under comparison, and the efficiency of the productive processes is not complicated by maintenance differences. Kleiber⁴⁷ compared the nutritive effects of the same basal ration differing only in the calcium percentage, one having 10 mg and the other 430 mg calcium per 100 grams food. The rats on the low-calcium diet had poor appetites, gained slowly; the rats on the high-calcium diet were restricted in feed consumption so that they gained at the same rate as those on the low-calcium diet. To reach body weight 146 grams (at 105 days), the low-calcium rats consumed 456 grams in contrast to 372 grams consumed by the high-calcium rats. The efficiency of dietary energy utilization (as measured by weight gains at the given dietary level) is thus 1.23 times as great on the high- as on the low-calcium level. This difference in feed utilization is attributed by Kleiber to (1) higher maintenance cost on the low-calcium diet (the basal metabolism at equivalent body weight for the low-calcium rats was 1.2 to 1.3 times that of the high-calcium rats); (2) higher calorogenic effect of the low-calcium diet; and (3) greater loss of unoxidized material in feces and urine on the low-calcium diet.

Which, then, of the above two major methods, *ad libitum* or *paired feeding*, should be used in the practical nutritional evaluation of foods or feeds?

There is, of course, no difference between the two if both rations are equally palatable and are consumed spontaneously in equal amounts.

⁴⁶ See, among his other papers, Mitchell, H. H., "Some essentials of a good nutrition experiment", *J. Nut.*, 2, 225 (1930), and 4, 525 (1931); *Science*, 66, 596 (1927); *J. Animal Sci.*, 2, 263 (1943).

⁴⁷ Mitchell, H. H., and Hamilton, T. S., *Proc. Am. Soc. Ani. Prod.*, p. 241, 1935. Kleiber, M., et al., *J. Nut.*, 19, 517 (1940).

The *ad libitum* method is the obviously correct one to use if it is desired to measure the relative appetite-stimulating properties of rations and, as explained in the preceding section, appetite for natural foods is normally a very important homeostatic factor. An appetite for, or good palatability of, a food normally indicates that it is a good food. Conversely, an appetite-depressing food is normally a poor food. Thus a food lacking in thiamine or calcium leads to loss of appetite, and the animal is much better off if it does not eat that food. Equalizing the food intake would, in this case, defeat the purpose for which the experiment is conducted, namely to discover which is nutritionally the better food. Normally, the greater the food consumption the greater the speed and economy of the productive process (growth, milk production, egg production, and so on) because of the reduced overhead maintenance cost per unit food consumed. Quoting Osborne and Mendel⁴⁸, "Economy of food can be effected only by supplying the young animal with as much as it will eat. . . . The practical feeder does not wish to know what quantity of a given protein is the smallest which he can use to secure a given amount of gain . . . rather . . . the greatest gain in the shortest time".

There are many experimental procedures, however, in which the paired-feeding method is superior, if not indeed the only useful one. For instance, if it is desired to evaluate the relative nutritional availability of calcium in the same milk before and after pasteurization⁴⁹, the differences in nutritional availability would easily be wiped out by slight differences in milk intake. Where the milk intake must be strictly equalized, the paired-feeding method is the only reasonable one to use. The results can then be presented quantitatively in a table or graph in which the availabilities of the raw and pasteurized milk are plotted against dietary levels. The criterion of calcium availability should, of course, be calcium storage, not weight gain or energy gain, unless it is also desired to investigate the influence of pasteurization of milk (not merely calcium) on weight gain or energy gain. The paired-feeding method should also be used for investigating the relative availability of, for example, butterfat and vegetable fat⁵⁰, in which case the criterion of availability may be weight gain or preferably energy gain.

Summarizing, two methods are employed for comparing the nutritional values of foods: (1) *paired-feeding*, or food-equalizing, which compares the nutritional effects at an arbitrary low level set by the animal which consumes the least food; and (2) *ad libitum* feeding which permits each animal to choose its own food-intake level.

The outstanding advantage of the paired-feeding method is that it eliminates the confusion in results due to differences in food intake which may mask the effects of differences in food composition. The disadvantages of the paired-feeding method are: (1) since the food intake is equalized, the

⁴⁸ Osborne, Mendel, and Ferry⁴⁸.

⁴⁹ Ellis, M., and Mitchell, H. H., *Am. J. Physiol.*, 104, 1 (1933).

⁵⁰ Deuel, H. J., Jr., *Science*, 98, 139 (1943).

effects of the differences in the food composition are not striking; (2) the differences in nutritional effects are obtained for one feeding plane, usually a low one (set by the less appetizing food) and, therefore, not the best plane for agriculturally productive purposes requiring the greatest food intake; (3) it does not indicate palatability differences in the food; (4) the animal on the better ration whose food intake is limited, is hungrier than its paired mate, and one may question whether animals differing in this respect are comparable⁵¹; (5) this method is not suitable for long-time investigation, including fertility and longevity.

The outstanding advantage of the *ad libitum* feeding method is that it places a premium on palatability, on food intake [often the best measure of nutritional quality of a feed or food, especially if the results are expressed in terms of efficiency (eq. 20.1)], or of its reciprocal, pounds feed consumed

Fig. 20.3. Curve (1) shows that the apparent biological value of protein declines with increasing protein percentage in the diet; curve (2) shows that the ratio of protein retained to feed ingested increases with increasing protein percentage in the diet up to about 40 per cent, in spite of the decline in biological value. This chart was prepared by the writer from data by T. S. Hamilton as quoted by H. H. Mitchell in 1937.

per pound live weight gained. From the agricultural viewpoint, the best ration is defined by the highest yield unit per feed consumed, regardless of feed consumption level (Fig. 20.3). Since the highest yield is usually associated with the highest food consumption level, the *ad libitum* method seems to be the more useful for practical comparisons of feed values.

Sherman and Campbell⁵² employ the *ad libitum* feeding method, interpreting the results by "the application of common sense" and the use of statistical methods (standard deviation, probable error, and coefficient of variation of the means). Growth criteria for rats include the rate of growth of the young during the first 28 days after weaning, gain in weight per 100 Calories of food consumed, gain per gram of protein con-

⁵¹ Boas-Fixsen, M. A., *Nut. Abstr. Rev.*, **4**, 450 (1934-35). Boas-Fixsen, *et al.*, *Bioc. J.*, **28**, 592 (1934).

⁵² Campbell, H. L., "Growth, reproduction and longevity as research criteria in the chemistry of nutrition", Dissertation, Columbia University, 1928. Sherman, H. C., and Campbell, *J. Biol. Chem.*, **97**, p. iii (1932); *Proc. Nat. Acad. Sci.*, **20**, 413 (1934).

sumed, Calories of food per gram of body weight per day, and average weights on the different diets at all ages.

The reproduction criteria include ability to bear and rear young, average weight of young at weaning time, length of breeding period, and age of sexual maturity. Longevity records are kept.

McCollum's method⁴⁴ for the long-range effects of proteins consisted in feeding diets containing the same percentages of the proteins under comparison, and observing the performance (growth rate, fertility, and lactation for 2 generations). McCollum kept no record of feed intake assuming that rats consume food in proportion to their caloric (not protein) needs. Nor did McCollum make adjustment for maintenance or digestion expenses.

Fig. 20.4a. Indicates that the higher the protein percentage in the ration (that is, the lower the nutritive ratio, which is the ratio of the digestible protein calories to the digestible non-nitrogenous calories) the lower the apparent "biological value" of the protein (p. 778).

20.4. Balance between nutrients. The above discussions on "nutritional wisdom" and "paired-feeding" methods indicate the dependence of nutritional welfare on a certain balance between the consumed nutrients.

The mechanisms whereby certain dietary interrelations affect health are known or suspected in some cases. It is known, for example (Ch. 6), that a

⁴⁴ McCollum, E. V., et al., *J. Biol. Chem.*, 47, 111, 139, 175, 207, 235 (1921).

certain amount of thiamine is necessary to oxidize in the body a given amount of carbohydrate. It is likewise clear that (when the protein in the diet is low) the proportion between the various dietary amino acids must approximate those in the body tissues, milk, egg, and so on, produced by the animal. It is also clear, for example, that there is some one proportion or balance between the (undigestible) roughage and the (digestible) concentrates in the

Fig. 20.4b. Indicates that the higher the apparent digestibility of a feed, the lower the apparent biological value of its protein. In other words, the apparent biological value of a protein varies inversely with its intake level (Ch. 4). There is no one definite biological value for a given protein. Figs. 20.4a and b, representing data on Holstein heifers, are from Swanson, E. W., and Herman, H. A., Univ. Missouri Agr. Exp. Sta. Res. Bull., 372, 1943 (see also pp. 757 and 778.)

ration which is optimal for the animal or for the productive process, such as milk production⁵⁴. Some roughage is needed to stimulate peristalsis; too much roughage may take up space needed for digestible foods, and stimulate excessive peristalsis, thereby disturbing the normal time relations in the digestive sequence. Or it may adsorb and sweep out digestive juices, enzymes, and digestible and even digested food. A dramatic illustration of balance between vitamins previously cited (Ch. 6) is the interrelation between biotin and avidin.

⁵⁴ Moore, L. A., and Huffman, C. F., "Bulk as a factor in formulating grain mixtures for dairy cattle", *J. Agr. Res.*, 44, 789 (1932). Cole, H. H., and Mead, S. W., *Science*, 98, 343 (1943).

Many types of necessary balance between foods or nutrients are not understood. For instance, dogs digest raw starch and raw egg when fed together, but cannot digest raw starch or raw egg when each is fed alone⁵⁵. Many other examples have been cited in the preceding section, such as that of Kleiber, who reported declining food utilization on declining calcium content in the ration, and that of Forbes, who reported declining food utilization on declining protein content in the ration. Similar declines in food utilization were reported on reducing phosphate⁵⁶ and other inorganic constituents⁵⁷. Mitchell⁵⁸ reported 40 to 50 per cent greater weight gains in chickens by adding one per cent common salt to a chick mash made up of 87 per cent corn, 10 per cent casein, 2 per cent cod-liver oil, and one per cent CaCO_3 .

The following discussion relates to the mutually supplementary values of, or the balance between, proteins containing different available amino acids. The discussion is necessarily confined to non-ruminants since, as above explained, they are not dependent on fine balance between the dietary amino acids.

If two or more proteins possess the same limiting amino acids, they will not supplement one another. For instance, wheat, linseed, and cottonseed meals do not supplement one another because they are all deficient in the same essential amino acids, *i.e.*, lysine and tryptophane. This explains the dramatic growth-accelerating effect of adding lysine and tryptophane to such rations (Fig. 20.5). On the other hand, milk and meat proteins (rich in lysine) and seed proteins (poor in lysine) do supplement each other. "Beef protein with a biological value of 69 and flour protein with a biological value of 55 when combined in proportion of 1 to 2 have a biological value of 73"⁵⁹. Likewise, while each alone, corn or tankage, is of low nutritive value, the two in combination make a satisfactory feed for swine⁶⁰. The extremely high supplementary value of milk to cereals is discussed in detail elsewhere⁶¹ (Sects. 20.2 and 21.2).

Heating often changes the biological value of proteins. For example, heating milk tends to reduce the biological value of its protein⁶² because milk contains lysine and cystine which are sensitive to heat. Beef-muscle proteins likewise suffer a reduction (about 10 per cent) in biological value on

boiling⁶³. The biological value of beans—especially soybeans—is, on the contrary, greatly increased by heating⁶⁴. The biological values of fish⁶⁵ and nut proteins are apparently unaffected by heating.

There is nothing novel about the idea that a diet or a ration needs to be well balanced for the needs of a particular process and that the waste of nutrients is least and the efficiency highest when the ration is most perfectly balanced. The novel aspect is the understanding of the mechanisms involved in terms of food composition and oxidation mechanisms (Ch. 6), especially in relation to the specific dynamic effect of foods (Sect. 2.3 and Ch. 4), and the relation between such avoidable wastes and thermodynamically unavoidable expenses (Ch. 2) in the efficiency complex.

Fig. 20.5. Lysine and tryptophane are dietary-essential amino acids as demonstrated by the curve showing cessation of growth when rats are fed on a diet in which zein (which lacks lysine and tryptophane) is the sole protein, and good growth when this diet is supplemented by lysine and tryptophane. The curves on the right show similarly that threonine is a dietary essential not only for growth but, judging by weight loss, also for maintenance.

Some of these ideas have been attractively, often dramatically, generalized such as Mitchell's: "Probably . . . unbalanced rations, like toxic substances, exert harmful effects in proportion to the amounts consumed . . ."⁶⁶ and "Each improvement in the nutritive balance of a ration improves the efficiency of its utilization. . . . It is a rational deduction from Liebig's 'law of the minimum' that a deficiency of a ration in an indispensable nutrient will impair the utilization of all other nutrients and hence the net energy of

the ration"⁶⁷; or Forbes⁶⁸ formulation of a "law of maximum normal nutritive value", to the effect that a perfectly balanced ration is one in which there are "no nutritive deficiencies to compromise the significance of the net energy value".

These generalizations about balance between nutrients must not be taken in too narrow a sense. A ration is balanced not at a sharply defined point but in a rather wide zone with considerable freedom of change in proportions between the nutrients. This elasticity of balance between nutrients is of great practical importance because it permits taking advantage of variability of supply and price of various dietary components.

The above generalization on dietary balance, moreover, needs broadening to include the time element, involving long-range effects, perhaps over several generations. For instance, it appears that very rapid growth in dairy calves induced by dietary means often leads in later life to particularly poor lactational performance. The same may be true as regards longevity, which may be depressed by rapid growth (Sect. 18.2.4). The method of assay by growth rate of rats is, perhaps, being over-emphasized. It was previously noted that some investigators judge the values of rations not only by growth rate but also by their effects on the whole life histories of the animals. This long-range method of dietary assay needs to be further extended.

20.5. General vitamin relations in nutrition. Chapter 6 was concerned with vitamins in relation to enzyme action in oxido-reduction processes. We shall here discuss the better-known aspects of vitamins in the nutrition of different species (Fig. 20.6).

It may be useful to recall that 15 vitamins have been isolated, namely, A, D, E, K, B₁ (thiamine), B₂ or G (riboflavin), B₆ (pyridoxine), C (ascorbic acid), niacin (nicotinic acid), pantothenic acid ("filtrate factor"), biotin, inositol, *p*-aminobenzoic acid, choline, and B₉ (chick antianemic factor, obtained from the norite eluate fraction of liver extract, probably identical with or a component of "folic acid", an essential growth-accelerating factor for *Lactobacillus casei*). There are several other vitamins which are not well known, such as vitamin P or citrin, vitamins^{69a} B₁₀ and B₁₁, and so on.

Not all these vitamins are needed in the diet of all species of higher animals. For instance, as previously explained, ruminants are not dependent on their feed for the water-soluble vitamins. Indeed, if they have access to bright sunshine, ruminants are dependent on their feed for only one vitamin, A, or rather for the provitamin A, carotene (plants have no vitamin A), and the demand for this vitamin in ruminants is very large, perhaps ten-fold the theoretical minimal need⁶⁹ because much of it is destroyed in the rumen.

⁶⁹ Hart, G. H., *Nut. Abstr. Rev.*, 10, 261 (1940).

Then, too, different species utilize carotene with different efficiencies. Poultry utilize it much more efficiently than cattle or even swine. Man can utilize about 60 per cent of dietary carotene, that is, the vitamin A equivalent of carotene for man is only a little over half that of fish oil vitamin A⁷⁰.

Fig. 20.6. Typical appearance of animals suffering from vitamin deficiency: deficiency of vitamin D in a calf (upper left), vitamin A in a calf (middle left), vitamin B₁ in a chick (lower left), scurvy in a guinea pig, nicotinic acid in a dog, vitamin A in swine, vitamin A in a chicken (upper right). From R. Graham and H. H. Mitchell, Circular 449, Univ. Ill. Agr. Exp. Sta.

The storage capacity for vitamins also differs. Vitamin A is rapidly stored in large amounts and used as needed⁷¹. Vitamin A appears to be needed by all species of mammals and birds.

Dietary ascorbic acid (and citrin?), on the other hand, is apparently needed by anthropoids and guinea pigs only.

⁷⁰ Booher, L. E., et al., *J. Nut.*, 17, 317 (1939).

⁷¹ Guilbert, H. R., and Hart, G. H., *J. Nut.*, 8, 25 (1934).

Dietary nicotinic acid is not needed by the rat, mouse, and chick, but it is apparently needed by the other species investigated (except, of course, ruminants).

Dietary thiamine, riboflavin, pyridoxine, and pantothenic acid are apparently needed by all species investigated (except ruminants), but variable amounts of these vitamins are also produced by microorganism in the digestive tracts of all species, even in man⁷².

Dietary vitamin E does not appear to be needed by goats and swine^{72a}, but it is definitely needed by the rat, mouse, hamster, guinea pig, rabbit, chick, turkey, dog, and duck.

p-Aminobenzoic acid is apparently produced by microorganisms in the digestive tract in sufficient amounts to meet all needs. This is indicated by the fact that feeding sulfa drugs (which inhibit these microorganisms from producing PAB, see Sect. 7.1) leads to deficiency symptoms, cured by administering of PAB^{72b}. Normally, biotin and vitamin K are apparently also produced by intestinal bacteria in sufficient amounts to meet all human adult needs. If, however, sulfanilimides are included, dietary vitamin K is needed by the rat, mouse, guinea pig, rabbit, pigeon, chicken, duck, goose, and canary, and dietary biotin is needed by chickens and turkeys.

Dietary choline is needed by the rat, rabbit, chicken, turkey, and dog.

Dietary inositol is needed by the mouse and chick.

The nature of the diet tends to influence the vitamin need, not only because of its effect on the vitamin-producing activity of intestinal microorganisms but also because thiamine, for example, is more involved in carbohydrate-rich⁷³ than in fat-rich or protein-rich⁷⁴ diets.

Some processes, especially reproductive, such as gestation, lactation, production of fertile eggs, appear to need extra vitamin supply.

Age influences the amount of dietary vitamin need. Old age is usually associated with decreased utilization and, therefore, with need for larger intake of vitamins⁷⁵. Youth and rapid growth also call for increased vitamins, but for different reasons. Heuser⁷⁶ believes that the riboflavin need in chicks is not proportional to the feed consumption or to the body weight of young animals but to the relative growth rate; during the first week of growth chicks require over threefold riboflavin per unit food consumed than during the eighth week.

The need for pantothenic acid is particularly high in early life when growth is most rapid. Thus rats seem to need four times the pantothenic acid at

3 weeks than at 10 weeks⁷⁷. Smaller-younger (growing) animals need more pantothenic acid per unit body weight than the heavier-older⁷⁸ animals.

As most vitamin investigations involving the use of highly purified diets have been conducted on rats, the dietary requirements of this species are best known. Several investigators, indeed, succeeded in growing rats on synthetic diets composed of dextrose, casein, hydrogenated oil or corn oil, and salt mixture supplemented with 8 vitamins: A, D, E, thiamine, riboflavin, pyridoxine, calcium pantothenate, and choline⁷⁹. The males were apparently fertile, but not the females. One group of investigators reported⁸⁰ that young could not be obtained on this diet even if supplemented with nicotinic acid because "in each case the female apparently destroyed the male".

More recent reports indicate rearing of rats through 3 to 4 generations on diets composed of dextrose, casein, hydrogenated oil, salts, cod-liver oil, supplemented with 6 other vitamins: thiamine, riboflavin, pyridoxine, nicotinamide, pantothenic acid, and choline⁸¹; or on diets composed of sucrose, casein, salts, corn oil, halibut-liver oil, supplemented with thiamine, riboflavin, pyridoxine, nicotinic acid, pantothenic acid, choline, and α -tocopherol⁸². The rearing is apparently associated with lactation difficulties.

Normal growth and fair reproduction in rats were observed by the Missouri investigators⁸³ on synthetic diets supplemented with 12 vitamins: A, D, E, K, thiamine, riboflavin, pyridoxine, pantothenic acid, nicotinic acid, choline, inositol and *p*-aminobenzoic acid. Some factors present in beef-liver extract and absorbed therefrom on fuller's earth increase the weaning percentage to 90 per cent and better, apparently by its favorable effect on the composition of the milk, because without it the young rats die, although the stomach is filled with milk. Yeast does not furnish the missing factor to rats⁸⁴ or rabbits⁸⁵. In some cases the difficulty may be quantitative; there may not be enough of certain vitamins in the diet. Lactation makes especially large demands on *p*-aminobenzoic acid, thiamine, and riboflavin⁸⁶. Such difficulties would not occur in ruminants that produce their own B vitamins.

The question of whether or not a given diet is adequate depends on the physiologic age and length of the experimental period. A given diet may be adequate for a short period at a given age but not for a longer period, or for another age interval. The following nitrogen-free dietary base has been recently used⁸⁷ for 4-week feeding periods in rats.

Thiamine hydrochloride.	224	mcg	Choline chloride.	134	mg
Riboflavin.	400	mcg	<i>p</i> -Aminobenzoic acid.	1.0	mg
Pyridoxine hydrochloride.	243	mcg	Cod-liver oil.	2	g
Calcium pantothenate.	1.5	mg	Corn oil.	10	g
Nicotinic acid.	2.5	mg	Salt mixture.	4	g
Starch and amino acids to make.	100	g

The optimal vitamin *proportions* in human nutrition are usually said to be 1 mg thiamine: 2 mg riboflavin: 10 mg nicotinic acid: 30 mg ascorbic acid: 4000 I. U. vitamin A: 400 I. U. vitamin D.

The quantitative aspects of vitamin need—the amounts required in relation to body size and to food consumption—have been discussed in Chapter 15. The conclusion there reached was that the B vitamins, which function as general metabolic catalysts, are needed in direct proportion to the total energy metabolism, or in direct proportion to the total caloric food intake. Thus the minimal thiamine need appears to be about 1 mcg thiamine per gram dry food consumed, or about 300 mcg per 1000 Calories energy metabolism. The optimal thiamine need is, perhaps, 500 to 1000 mcg (0.5 to 1.0 mg) per 1000 Calories metabolism. The minimum riboflavin need per food Calorie appears to be about twice the minimum thiamine need.

The need for the specialized fat-soluble vitamins, and particularly for vitamin A, seems to be in proportion to simple body weight rather than to energy metabolism. The minimal vitamin A need appears to be 2 to 4 mcg per pound live weight, regardless of species.

Because of the large literature on the quantitative vitamin needs of different animals, the quantitative data together with the references are presented in the following tables prepared with the cooperation of Dr. V. F. McRoberts.

Special attention is called to the wide range of data by Guilbert and associates and the remarkable consistency of the ratio of vitamin A to unit body weight in animals of such wide range in live weight. The vitamin A need for poultry (data not by Guilbert) appears to be much higher than for mammals.

In this connection it may be helpful to have recorded the quantitative vitamin unit equivalents. Vitamin A is usually represented in I. U. (International Units) or U. S. P. units (identical with I. U. for vitamin A); thiamine and riboflavin in mg or in mcg (micrograms or gamma, which is 1/1000 mg or 1/1,000,000 g); ascorbic acid and nicotinic acid in mg. The equivalents are:

- 1 I. U. vitamin A = 1 U. S. P. unit = 0.6 mcg B-carotene. (The Sherman-Munsell unit of vitamin A, about 1.4 I. U. vitamin A, is defined by the amount needed to support growth in a "standard rat" for 8 weeks at the rate of 3 g per week.)
- 1 mg thiamine = 333 I. U.
- 1 I. U. thiamine = 3 mcg thiamine hydrochloride
- 2½ mg riboflavin = 1000 I. U.
- (1 Sherman-Bourquin unit riboflavin = 2.5 mcg or
- 1 mcg = 0.4 Sherman-Bourquin unit)
- 1 mg l-ascorbic acid = 20 I. U.
- 1 Sherman unit ascorbic acid = 10 to 15 I. U.
- 1 I. U. vitamin D = 0.025 mcg crystalline vitamin D, or
- 1 mcg vitamin D (calciferol) = 40 I. U.
- 1 Steenbuck unit vitamin D = 3.3 I. U.

The vitamin content of food is often expressed in terms of micrograms per 100 gm of the food. It is useful to remember that 100 g is 3½ oz, the usual weight of a serving (3½ oz = 99.2 g; 4 oz = 113.4 g).

The minimal vitamin need is estimated⁸⁸ by the minimal intake which permits normal growth and development in the young of a given age; or in adults the minimal intake which prevents development of typical lesions and/or loss in weight. The minimal amount of the vitamin required to cure deficiency symptoms is also used. The latter method gives higher values and some of the published differences in vitamin need are due to these differences in method employed. Vitamin A deficiency in man by the dark-adaptation method as used by Booher is more sensitive than the night-blindness test used by Guilbert, with corresponding apparently higher vitamin A needs in man than in farm animals.

The estimation of the amounts of vitamin in food⁸⁸ is done in several ways, including chemical determination, growth rate of an appropriate assay animal, and for the members of the B complex vitamins, by microbiologic methods.

Since yeast, molds, bacteria are specific in their nutritive requirements, the growth rate of the microorganism under controlled conditions is directly proportional to the vitamin concentration in the test substance. Various strains of yeast (*Saccharomyces cerevisiae*) are used for estimating⁸⁹ thiamine, pyridoxine, biotin, inositol. Growth rate is measured by the rise in medium turbidity or CO₂ accumulation. Pyridoxine may also be measured⁹⁰ by weighing the mycelium of the mold *Neurospora sitophila*. *Lactobacillus casei* is employed⁹¹ for estimating riboflavin, biotin, and pantothenic acid. The measurement consists in titrating the lactic acid produced during a given growth period. *Lactobacillus arabinosus* is employed⁹² for estimating niacin.

Ascorbic acid is usually estimated by the chemical method of Bessey and King⁹³. The food sample is extracted and the extracted ascorbic acid is titrated with 2,6-dichlorophenolindophenol, a deep purple dye in neutral solution. The dye is reduced by the ascorbic acid to a colorless form. The quantity of dye reduced is a measure of the ascorbic acid. Certain types of materials, however, yield misleading results, in which case the Sherman guinea pig method is used⁹⁴.

Depending on the nature of the material tested, vitamin A may be estimated (for fish oils) spectrophotometrically or colorimetrically through its reaction with antimony chloride or (for plant material) extracting the carotene pigments and estimating, or by the growth method⁹⁵.

Vitamin D is estimated by confining young rats for 3 weeks to a ricket producing diet, followed by 8-day feeding of the test material. On the eleventh day the animal is sacrificed and the tibia, or radius, or ulna dissected out, cleaned, finally immersed in silver nitrate solution and exposed to light. Silver is deposited where calcium is present in the metaphysis of the bone forming a dark line, indicating the extent of calcium deposition, and the degree of healing due to feeding the test food. This is the "line test"⁹⁶ for vitamin D. Other methods are also used, such as roentgenological examination of the animal or determination of the bone ash.

Vitamin K is estimated by the blood clotting time⁹⁶.

To sum up, this section discusses briefly the known vitamins important in nutrition, lists and discusses data in tabular form, together with references to the literature on vitamin needs of different species and the influences of several conditions (age, growth rate, etc.) on these needs (see following tables). To render the vitamin needs concretely, one may inspect Tables 20.1 to 20.1e (appendix) showing the dietary standard needs in human

Minimum Vitamin A Requirements
(1 I.U. vitamin A = 0.6 mcg β -carotene = 0.21 mcg vitamin A)

Species	Reported requirement		Requirement (mcg/lb. body wt/day)		Ref.
	β -Carotene	Vitamin A	Carotene	Vit. A	
Rat	15-20 mcg/kg/day	4.6-5.3 mcg/kg/day	7-9	2-3	1
Dog		23-43 I.U./kg/wk		2-4	2
Poultry:					
600-g. chick		150 I.U./100 gm feed			3
8 wks. old			50		4
Chicks	125 mcg/100 gm feed	80-160 I.U./100 gm feed	15-30		5
Birth-12 wks.	50-100 mcg/100 gm feed		55-70		6
12 wks. maturity	200 mcg/100 gm feed		50		6
Laying hens	500 mcg/100 gm feed				6

nutrition and the composition of some foods in Table 20.2. The following values in relation to the daily standards for a 70-kg (145-lb) person may also be helpful.

Vitamin A need: 5000 I.U. a day, about 75 I.U. per kg body weight. A 100 g or 3½ oz portion of beet tops contains about 21,000 I.U. vitamin A (in the form of carotene); spinach 8000 I.U.; mustard greens 11,000 I.U.; carrots 1000 I.U.; squash 1000 I.U.; sweet potato 11,000 I.U.; liver 9000 I.U.; butter 2500 I.U.

Thiamine need: 1.8 to 2.3 mg a day. A serving of 100 g or 3½ oz pork contains about 1.4 mg thiamine, nearly the full daily need, but 100 g fish or poultry supplies only 0.12 mg; 100 g (4 slices) whole-wheat bread supplies about 0.3 mg, but white bread supplies only 0.09 mg; 1 oz dry brewers yeast 1.6 mg; 1 pint milk, 1 oz peanuts, 10 oz oatmeal, 5 oz potatoes, each supplies about 0.22 mg; 1 egg supplies 0.12 mg.

Riboflavin need: 2.2 to 3.3 mg per day. 100 g (3½ oz) portions supply the following amounts of riboflavin: liver 2.5 mg; beef heart 0.7 mg; beef chuck 0.3 mg; fish, as cod or haddock, 0.2 mg; 1 pint milk 1.0 mg; 1 egg 0.2 mg.

Niacin or nicotinic acid need: 15–25 mg per day, 100 g or 3½ oz portions contain the

Minimum Thiamine Requirements

Species	Reported requirement	Calculated requirement (mcg/100 gm diet)	Ref.
Mouse	10 mcg/mouse/day		1
Rat	80–100 mcg/100 gm diet 12.5 mcg/rat/day ^a	80–100 125–250	2 3
Chicks	60 mcg/100 gm diet	60	4
Chicks & turkeys	60 mcg/100 gm diet	60	5
Chicks	130–150 mcg/100 gm diet	130–150	6
Dogs:			
Low-fat diet	75 mcg/100 gm diet	75	7
56.5%-fat diet	27.5 mcg/100 gm diet ^b	75	7
Swine	1 mcg/100 lbs/day ^c 37 mcg/kg/day 80–94 mcg/100 gm feed ^d	50 80–94	8 9 9
Man	0.22 mg/1000 Calories of diet ^e	88–110	10
Infant	80 units/day		11

^a It is assumed that a growing rat will eat between 6 and 12 grams of feed daily.

^b The author of the reference cited based this figure on 100 grams protein and carbohydrate of the high-fat diet

^c It is assumed that a pig weighing about 100 lbs will consume approximately 2 kg feed per 100 lbs live weight per day.

^d The authors of this report estimate that their ration contained 75 per cent carbohydrate and protein; using this figure, they conclude that growing pigs require between 106 and 125 mg thiamine per 100 grams carbohydrate and protein.

^e It is assumed that 1 gram of diet is equivalent to 4 or 5 Calories.

following amounts: liver 20 mg; pork 8 mg; dried brewers yeast 50 mg; beef or fish 6 mg; veal 10 mg; whole-wheat bread 2 mg and white bread 0.75 mg.

Ascorbic acid need: 75 mg a day, approximately 1 mg per kg body weight. ¼ grapefruit (7 oz) contains 80 mg; 1 orange (5.5 oz) 75 mg; 100 g fresh raw cabbage 80 mg; 100 g lettuce 15 mg; 100 g green pepper 170 mg; 100 g tomatoes 30 mg; 100 g lemon, grapefruit, orange, or tangerine 45 mg; 100 g or 100 cc juice of lemon, grapefruit, or orange 40 to 50 mg; 100 g peeling of lemon, grapefruit, or orange 200 mg; 100 g turnip or potato 30 mg; 100 g carrots 7 mg.

20.6. Vitamins in relation to the neuro-endocrine and neuro-muscular systems. The relation of vitamins to the nervous system is of particular human interest not only because the mental condition in man is particularly

important, but also because man manifests certain mental disorders not shown clearly or investigated conveniently in laboratory or farm animals. This is, of course, due to the high development of the human brain (Fig. 10.1, and Sect. 10.9), affording a favorable substrate for the development of mental disorders, to the relatively slow growth rate (Ch. 16) and long life span (Chs. 18 and 19), which permit slow-acting nutritional deficiencies to produce pronounced nervous and mental effects.

Estimated Riboflavin Requirements

Species	Reported requirement	Requirement calculated to mcg/100 gm feed	Reference
Rat	10 mcg/rat/day ^a	80-160	1
	18 mcg/rat/day ^b	144-288	2
Poultry:			
Chicks	290 mcg/100 gm feed ^c	290	3
Chicks	60 Sherman units/100 gm feed	150	4
Chicks	100-350 mcg/100 gm feed	100-350	5
Chicks	190-200 mcg/100 gm feed	190-200	6
Hens	230 mcg/100 gm feed	230	3
Egg production	100-130 mcg/100 gm feed	100-130	7
Hatchable eggs	245 mcg/100 gm feed	245	7
	2.5 mg/lb. feed	573	8
	220-230 mcg/100 gm feed	220-230	6
Dog	200-400 mcg/100 gm feed ^d	200-400	9
	11.3 mcg/lb/day		10
Swine	1-3 mg/100 lb/day ^e	50-150	11
Man	35-60 mcg/kg/day ^f		12

^a It is assumed that a growing rat will eat about 6-12 gm feed daily. The value 10 mcg/day was not reported as a minimum requirement; it merely represents the level fed in a purified diet which was used in studying a deficiency of pyridoxine.

^b It is again assumed that a young rat will consume about 6-12 gm. feed daily. The value 18 mcg/day was the minimum amount of riboflavin which would support normal growth on a low-fat diet; it was not enough to support growth on a high-fat diet.

^c 1 mcg = 0.1 Bourquin-Sherman Unit.

^d Judging from Elvehjem's data and the fact that he fed the supplement only once a week, it is believed that the minimum riboflavin requirement of the dog is nearer to 200 than to 400 mcg/100 gm feed.

^e It is assumed that a pig will eat about 2 kilograms of feed per 100 lbs live weight per day.

^f These values for man are based on the amount necessary to maintain normal levels of riboflavin in the urine. Sebrell states that the minimum daily requirement is nearer to 35 than to 60 mcg per kilogram of body weight.

Because of their intimate integrative effects on the organism as a whole, it is often difficult to separate nervous from endocrine disorders. For instance, as shown by Pavlov, Cannon, Crile, and younger contemporaries, the nervous system acts on the adrenals, thyroid, pituitary, gonads, islets of Langerhans, and other glands, and the secretions of these glands in turn act on the nervous system, in a sort of a circle, sometimes (in disease) in a vicious circle (Sects 10.8 and 18.2.3).

The dietary influence on the endocrines may be of specific or general nature. For instance, iodine deficiency leads to various thyroid abnormalities, ranging from relatively harmless goiter to hopeless cretinism⁹⁷. This is understandable, since iodine constitutes 65 per cent of the thyroid hormone. Some

Nicotinic Acid (Niacin) Requirements

Species	Reported requirement	Reference
Dog	0.2-0.5 mg/kg/day	1
	0.5-1.5 mg/kg/day	2
	10 mg semi-weekly ^a	3
	0.25 mg/kg/day	4
Monkey	2.5 mg/kg/day	5
Swine	13.7 mg/100 lbs/day ^b	6
	2 mg/kg/day ^b	7

^a The dog used in this experiment weighed 7.25 kg.

^b These values for swine represent levels of niacin fed as supplements to a purified diet and do not necessarily represent the minimum requirement for swine.

excess iodide intake is, on the other hand, harmless; it is excreted. Less specific are the thyroid hypertrophy in vitamin A deficiency (McCarrison, Sure), and thyroid depression [including depression of the metabolism accelerating effect of thyroxine (Drill, Drummond)] in vitamin A excess⁹⁷.

⁹⁷ See Section 7.3.2A for the literature.

Ascorbic acid also affects the thyroid. Massive ascorbic acid depresses the metabolism-accelerating effect of thyroxine (Belasco and Murlin), and ascorbic-acid deficiency (in guinea pigs) hypertrophies the thyroid with hemorrhagic infiltrations and affects adrenocortical hormone production.

A curious effect of thyroid is that in its absence carotene cannot be converted into vitamin A. While normal herbivores fed good roughage do not suffer from vitamin A deficiency because they utilize the carotene in the roughage, thyroidectomized herbivores develop serious lack of A on good roughage.

It would, then, appear that hyperthyroidism and Graves disease would be ameliorated by massive doses of ascorbic acid and vitamin A, especially since hyperthyroidism tends to damage the liver and thus interfere with vitamin A storage, and that hypothyroid individuals, not able to utilize carotene, should be fed vitamin A as such (not carotene).

Since thyroxine accelerates the metabolic rate of all nutrients, including vitamins, the accelerated metabolism of hyperthyroidism is likely to develop into dietary deficiency for some nutrient consumed at a relatively low level. This special deficiency may mask or confuse the thyroid abnormality. For instance, the high pulse rate associated with hyperthyroidism may be confused with or masked by the low pulse rate associated with thiamine deficiency.

Similarly, vitamin D and calcium deficiency may be the outstanding symptoms in hyperthyroidism since, under the influence of thyroxine, the rate of calcium catabolism tends to parallel that of energy and nitrogen metabolism.

One of the very interesting relations between an endocrine and a vitamin is that between the parathyroid and vitamin D, both of which are regulators of calcium and phosphorus metabolism, but in different ways (Sect. 7.5). While the primary function of the parathyroid is to maintain constant the blood-calcium level, that of vitamin D is to catalyze calcium assimilation into bone. The parathyroid weight increases with increase in calcium demands. Thus while the parathyroid weight of a non-milking goat is 100 mg, that of a milking goat is 170 mg⁹⁸. Animals without parathyroids, on the other hand, may be maintained indefinitely by high calcium and vitamin D intake, and the same holds true for high-milking dairy cows (when the parathyroid may not be able to meet the demands made on it) which may be maintained in good calcium condition, avoiding milk fever, by high calcium and vitamin D intake (Sect. 7.5).

Vitamin E deficiency, if severe enough, leads to such atrophy of the an-

⁹⁸ Campbell, I. L., and Turner, C. W., Univ. Missouri Agr. Exp. Sta. Res. Bull. 353, 1942.

terior pituitary (in rats) as to amount to virtual hypophysectomy as regards reproduction⁹⁹.

Vitamin E deficiency also leads to nutritional muscular dystrophy, and a spastic ataxia-like paralysis in guinea pigs and rabbits¹⁰⁰, and to nutritional encephalomalacia in chicks¹⁰¹, characterized by Parkinsonian-like tremors and head retraction and rotation. It has been known¹⁰² since 1928 that the lack of a dietary factor (present in wheat-germ oil) leads to degenerative changes in the neuro-skeletal system.

Cod-liver oil appears to have something that counteracts the anti-paralysis action of vitamin E¹⁰³. The apparently injurious effect of cod-liver oil on herbivora¹⁰⁴ may be due to an "antagonism" between E and some anti-vitamin E factor in the oil; or, when rancid, it may destroy the vitamin E by autoxidation^{104a}.

While what is now called thiamine deficiency was the first to be investigated in relation to nervous function¹⁰⁵ (in 1897 Eijkmann published his report on polyneuritis in chickens¹⁰⁶ and in 1911 Funk prepared the beriberi-curative substance from rice polishing and called it vitamine), perhaps all B vitamins involved in carbohydrate metabolism are needed for normal nervous function because the nervous system, particularly the brain, apparently obtains its energy from oxidation of carbohydrate alone¹⁰⁷. Even diabetics not receiving insulin have a brain R.Q. which is virtually unity¹⁰⁸, indicating that the brain always obtains its energy from carbohydrate oxidation. Since, therefore, the function of the nervous system depends on the energy supplied by carbohydrate with the aid of catalysts involving certain vitamins as prosthetic groups, it is obvious that deficiency of vitamins, which interferes with carbohydrate oxidation¹⁰⁹, will lead to dysfunction of the nervous system. It has, indeed, been shown that the arterio-venous oxygen difference is about 25 per cent lower and the arterio-venous sugar difference is about 60 per cent higher in persons suffering from severe vitamin B complex deficiency (pellagra) than in normal persons¹¹⁰. As the deficiency pro-

gresses, various nervous and psychic manifestations follow, such as neuritis, neuralgia, nervousness, anxiety, fatigue, mental confusion, and so on, and perhaps also such diseases as migraine and sciatica. The longer the period on the deficient diet, the more severe the dysfunction. The ataxia-like Vernicke's syndrome in man (due to alcoholism), or Chastek paralysis in foxes^{110a}, is apparently an advanced state of thiamine deficiency.

As previously explained (Ch. 3 and 6) energy is required to maintain the integrity of living tissue, and when this maintenance energy is not available, the tissue disintegrates. Nervous tissue is particularly sensitive to deficiency of maintenance energy, as indicated dramatically by the "black out" in high-altitude flying as result of brief oxygen deficiency, and it is reasonable to assume that the deficiency of a limiting vitamin involved in carbohydrate oxidation may lead to injury, depending on the severity and duration of deficiency. This appears to be certain as regards deficiency of thiamine¹¹¹, riboflavin^{111, 112}, pyridoxine^{112, 113}, and nicotinic acid¹¹⁴, all of which are of great clinical importance.

Vitamin A deficiency may lead to generalized peripheral nerve lesions¹¹⁵ (Fig. 20.6). It is, however, believed¹¹⁶ that the injury to the nervous system by vitamin A deficiency in early life may be not directly on the nerves but by retarding skeletal growth; this leads to injury of the nervous system by undue crowding, or similar mechanisms. Thus Moore¹¹⁷ observed a constriction of the optic foramen and, therefore, of the optic nerve, with consequent blindness, in vitamin A-deficient calves. Vitamin A deficiency may similarly lead to increased intracranial pressure with associated disorders of the central nervous system and of behavior.

Summing up, it appears that some endocrine, nervous, mental, and muscular disorders, including "shifting pains", may be associated with disturbed intermediate metabolism as result of deficiency of vitamins, particularly of thiamine, nicotinic acid, pyridoxine, and riboflavin, and by different mechanisms as result of deficiency of vitamins A, E, D, and biotin.

20.7. Amino acid relations in nutrition¹¹⁸. It has been explained (Sect. 20.1) that species differ as regards dependence on their diet for vitamins,

¹¹⁸ For extensive discussion of the amino acid and protein literature, see Mitchell, H. H., and Hamilton, T. S., "The biochemistry of amino acids", Reinhold Pub. Corp., New York, 1929. Schmidt, C. L. A., ed., "The chemistry of amino acids and proteins", 1938, and "Addendum, the chemistry of amino acids and proteins", C. C. Thomas, Springfield, Ill., 1943.

because some vitamins are synthesized by microorganisms in the digestive tract, some are synthesized by body tissue, and some apparently do not need certain vitamins for their metabolic processes¹¹⁹. The situation is similar as regards amino acids. Ruminants appear to be more or less independent of dietary amino acids because, like the B-vitamins, amino acids are synthesized from simpler nitrogen compounds by rumen microorganisms (Sect. 20.1). This discussion is, therefore, necessarily concerned with non-ruminants, mostly rats and mice, because the experimental work was practically confined to these species.

About 1907 Wilcock and Hopkins¹²⁰ observed that mice lose weight when the dietary protein is confined to zein (from corn) unless supplemented by tryptophane. About 1912 Osborne and Mendel¹²¹ demonstrated that rats whose only source of protein was zein were definitely dependent for their growth on lysine as well as on tryptophane supplements. Quite recently Rose¹²² and associates demonstrated that threonine and methionine are essential amino acids (Fig. 20.5). And now it is believed that (for growth of rats) 9 amino acids are absolutely indispensable, 9 are dispensable, and 4 are partly dispensable. The meaning of "partly dispensable" is illustrated by arginine¹²³, which is synthesized in the body but at a relatively slower rate than are the other dispensable amino acids. The same is true of glycine for chickens^{123a}. The dispensable ones are synthesized by the body or by gut bacteria.

It is believed that methionine can replace cystine, at least in part, but that cystine cannot replace methionine¹²⁴; yet cystine appears to be a limiting factor in the growth of animals in which (cystine-rich) hair is a major part of the growth, such as for growth of sheep wool¹²⁵ and rat hair¹²⁶, which contain 13 per cent cystine and 0.5 per cent methionine. Certain cystine-poor proteins, such as casein and white-bean protein, which contain methionine, do not support satisfactory growth without the addition of cystine.

The dietary essential amino acid needs undoubtedly vary with the essential amino-acid composition of the body tissues. Roughly speaking, half of the muscle protein is composed of the essential amino acids and contains¹²⁷ 8 to 9 per cent lysine, 6 to 8 per cent arginine, 4 to 5 per cent each of threonine, serine, tyrosine, and phenylalanine, 3 to 4 per cent methionine, 1.8 to 2.4 per cent histidine, 1.1 to 1.4 per cent cystine, 1.2 to 1.4 per cent trypto-

phane. It works out that for every 10 molecules of lysine there are in the muscle tissue approximately 9 of serine, 7 each of arginine and threonine, 4 each of phenylalanine and tyrosine, 3.5 of methionine, 2.5 of histidine, and about 1 each of tryptophane and cystine. The visceral organs (in contrast to muscle) contain less lysine, more cystine, serine, phenylalanine and tryptophane.

The three categories of amino acids—indispensable, dispensable, and partly dispensable—are listed in the following table. The numerals in parentheses indicate the proportions of the indispensable amino acids (active form) required to support growth in rats fed at certain levels¹²⁸.

Three amino acid categories.

Nutritionally indispensable (for rats)		Partly dispensable	Dispensable
Tryptophane	(0.2)	Arginine (0.2)	Alanine
Lysine	(1.0)	Cystine	Glutamic acid
Phenylalanine	(0.7)	Tyrosine	Hydroxyglutamic acid
Histidine	(0.4)	Glycine	Aspartic acid
Threonine	(0.6)		Serine
Methionine	(0.6)		Proline
Leucin	(0.9)		Hydroxyproline
Isoleucin	(0.5)		Citrulline
Valine	(0.7)		Norleucine

The following numerical estimates¹²⁹ of the amino acids, in several food proteins are instructive.

Percentage amino acid make-up of meat, milk, eggs, and related food proteins.

Amino Acid	Meat	Milk	Casein	Egg	Wheat	Wheat germ	Yeast	Soybean
Leucine	12	15	12	19	13	7.0	13	8
Lysine	8.1	7.5	6.9	6.0	2.7	5.5	6.0	5.4
Arginine	7.1	4.3	4.1	7.0	3.0	6	4.3	5.8
Phenylalanine	4-5	5.7	5.2	5.6	8.7	4.2	4.1	5.3
Threonine	4.3	4.6	3.9	4.9	3.3	3.8	5.0	4.0
Valine	3-4	5	7	4-5	3-4	3-5	4-5	4-5
Isoleucine	3.4	4.4	5	5.3	4	3	3-4	4
Methionine	3.3	2.8	3.5	4	3.0	2.0	2	1.8
Tyrosine	3.1	5.3	6.4	5.0	3.8	3.8	4.2	4.1
Histidine	2.2	2.5	2.5	2.4	1-2	2.5	2.8	2.3
Tryptophane	1.2	1.6	1.5	1.6	1	1.0	1.4	1.5
Cystine	1.1	1.1	0.4	2.1	1.3	1	1.3	0.6

A given amino acid, or an amino-acid derivative, may be particularly important in one but not in another metabolic process. Thus, according to

¹²⁸ This problem is still under investigation and debate. See, for example, Kinsey, and Grant⁸⁷.

¹²⁹ Block, R. J., and Bolling, D., *J. Am. Diet. Assn.*, 20, 69 (1944).

Hammett¹²⁰, histidine is particularly useful in maintenance (rather than growth); sulfhydryl in cell proliferation (rather than maintenance); proline in cell differentiation (rather than proliferation); arginine in growth initiation; adenine and guanine in cell segregation (organization); the alpha amino acids in increase of cytoplasmic mass.

There are obvious difficulties in precise apportioning of amino-acid functions because of the intimacy between the several growth sequences. For instance, a given amino-acid necessary for maintenance must also be necessary for growth, since there can be no growth without maintenance.

What was said about the effects of vitamin deficiency is applicable to amino-acid deficiency, as the amino acids also enter into the building of various "carriers" from hemoglobin to enzymes.

The amino acids are characterized by their amino group, NH_2 . The amino acids are usually divided into the following classes.

1. Monocarboxylic amino acids: glycine, alanine, valine, isoleucine, norleucine
Typical formula: $\text{CH}_3 \cdot \text{NH}_2 \cdot \text{COOH}$, glycine or amino acetic acid
 $\text{CH}_3 \cdot \text{CHNH}_2 \cdot \text{COOH}$, alanine or α -amino propionic acid
2. Dicarboxylic amino acids: aspartic acid, glutamic acid
Typical formula: $\text{HOOC} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{CHNH}_2 \cdot \text{COOH}$, glutamic acid or α -amino glutaric acid
3. Hydroxyamino acids: serine, threonine, hydroxyglutamic acid
Typical formula: $\text{CH}_2 \cdot \text{CHOH} \cdot \text{CHNH}_2 \cdot \text{COOH}$, threonine or α -amino β -hydroxybutyric acid
4. Aromatic amino acids: phenylalanine, tyrosine
Typical formulas: $\text{C}_6\text{H}_5 \cdot \text{CH}_2 \cdot \text{CHNH}_2 \cdot \text{COOH}$, phenylalanine or α -aminophenyl-propionic acid
 $\text{HO} \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{CHNH}_2 \cdot \text{COOH}$, tyrosine or α -amino β -p-hydroxyphenyl-propionic acid
5. Indole amino acid: tryptophane, β -indole- γ -amino-propionic acid has the formula:

6. Sulfur-containing amino acids: cystine, methionine.
7. Basic amino acids: lysine, histidine, arginine:
Typical formula: $\text{H}_2\text{N} \cdot (\text{CH}_2)_4 \cdot \text{CHNH}_2 \cdot \text{COOH}$, lysine
8. Pyrrole-containing amino acids: proline, hydroxyproline

Since the value of a protein depends on its amino acids, the designation "crude protein" (rather than "true protein") is used in feed analysis. This includes all nitrogen multiplied by 6.25 (assuming that protein contains 16 per cent N, so that $100/16 = 6.25$). The non-protein nitrogen is not all peptide and amino acid, but only roughages, as alfalfa, are heavily loaded with non-amino nitrogen¹²¹, which is utilized by ruminants.

¹²⁰ Hammett, F. S., *Growth*, 6, 59 (1942).

¹²¹ Jones, D. B., "Factors for converting percentages of nitrogen in foods and feeds into percentages of protein", U. S. Dept. Agr. Circ. 183, 1931. Hart, E. B., and Bentley, W. H., "Water-soluble nitrogen in feeding stuffs", *J. Biol. Chem.*, 22, 477 (1916).

As previously noted (Sect. 20.4), if one of the essential amino acids is lacking, the other amino acids cannot be used for protein building, with the result that they are deaminized and the nitrogen is eliminated with the associated "specific dynamic effect" (Ch. 4). The non-nitrogen residue (lactic acid, pyruvic acid, pyruvic aldehyde) may be transformed into sugar as indicated by the following diagrammatic equations (Sect. 6.3).

The urea is eliminated and the sugar is retained.

Under certain conditions these reactions are reversed, and alanine is formed from lactic acid and pyruvic aldehyde. This may explain the production of the dietary dispensable amino acid in the body (Sect. 6.5). There are always NH_3 compounds and carbohydrate intermediate compounds in the body from which such amino acids may be produced. Moreover, glycerol ($\text{CH}_2\text{OH} \cdot \text{CHOH} \cdot \text{CH}_2\text{OH}$, from dietary fat) is related, through glyceraldehyde ($\text{CH}_2\text{OH} \cdot \text{CHOH} \cdot \text{CHO}$), to pyruvic aldehyde ($\text{CH}_3 \cdot \text{CO} \cdot \text{CHO}$). These relations indicate the possibilities of amino acid synthesis in the body from NH_3 compounds and carbohydrate (α -hydroxy-acids as lactic acid, α -ketonic acid as pyruvic aldehyde); these relations also indicate how under certain conditions protein is converted to carbohydrate^{132, 133} (up to 58 per cent) and how fat is converted to carbohydrate¹³⁴.

The nutritional value of the digestible part of a protein when fed at a low level, depends on the proportion of the essential and semi-essential amino acids in the food in relation to the proportions required by the body. As explained previously (Sect. 20.4), the supplementary value of proteins is their ability to supplement each other's deficiencies. For instance, the nutritional value of grain protein is increased by the addition of milk because the amino acids in milk protein make good the amino-acid deficiencies in grain protein; the unfavorable influence of heat on some proteins is due to the injury of a limiting amino acid, and so on.

There are many empirical methods of representing the numerical value of protein, some of which were discussed in Sect. 20.3. The writer likes the method of McCollum and Parsons (eq. 20.3), which represents the protein value in terms of the ratio of nitrogen retained to nitrogen consumed under a given set of conditions. Another interesting way of representing the protein value is in terms of some standard protein value. It has been suggested¹³⁵ that the value of proteins be expressed in terms of milk-protein replacement values.

Thomas¹³⁶ and more recently Mitchell¹³⁷ defined the nutritive value of protein in terms of "biologic value", the percentage of absorbed (from the digestive tract) nitrogen which is retained, that is, which is not excreted in the urine as exogenous nitrogen. This

concept is more complex than appears. In the first place the biological value of protein as thus defined may be only remotely related to its actual nutritional value. For instance, wool, hair, feathers may have a high biological value but no real nutritional value because of the insignificant digestibility of wool, hair, and feathers; the biological value of protein is not concerned with digestibility, but only with the retention of that part of the protein which is digested and absorbed into the body proper. Thus, cocoa protein and navy-bean protein have¹³⁸ the same biological value, 38 per cent; but since the digestibility of cooked navy-bean protein (76 per cent) is twice that of cocoa protein (38 per cent), the real nutritional value of cooked navy-bean protein is twice (29 per cent) that of cocoa protein (14 per cent) in spite of the same biological value. Proteins, such as zein, on the other hand, are highly digestible but lack lysine and tryptophane; so is gelatin, which lacks tryptophane. But McCollum's definition takes care of both digestibility and amino-acid balance.

Protein Values of Foods for Maintenance and Growth: Level of Protein Feeding,
8 to 10 per cent.

(From Mitchell and Hamilton, except last column.)

Food	Water Con- tent ¹ %	Protein Con- tent ¹		Quality of Protein		Metabolic Pro- tein in Feces		Net Protein Value of Food		Net Protein Value of Protein ⁴ %

¹ Average analyses taken, as far as possible, from Bull. 28 (revised), Office of Experiment Stations, U. S. Dept. Agr.

² The metabolic nitrogen in the feces is assumed to equal 0.23 gram per 100 grams of dry matter of food. See Bull. Natl. Research Council, 1926, xi, pt. 1, no. 55, p. 23.

³ Cooked.

⁴ Product of digestibility and biological value of the protein, assumed to represent the percentage of the intake protein retained for maintenance or growth.

Mitchell and Hamilton also employed McCollum's definition but called it "net protein value", comparable to the net energy value of feed (Sect. 2.3) illustrated in the following statement and table from these authors¹³⁸.

A cut of lean-beef round contains 21.3 per cent protein, 96 per cent of which is "really" digestible (that is, not including the metabolic nitrogen in the feces with the indigestible material). Hence, this beef round contains $0.96 \times 21.3 = 20.4$ per cent *digestible* protein. When this meat is fed to rats at 8 to 10 per cent protein level in the diet, its biological value is 69 per cent; hence the net protein value of this cut of meat is $0.69 \times 20.4 = 14.1$ per cent. A part of the metabolic nitrogen (that part related to the amount of food

¹³⁸ Mitchell, H. H., and Hamilton, T. S., "The biochemistry of amino acids", Reinhold Pub. Corp., pp. 555-556, 1929.

intake) in the feces may be charged to this "net protein". Mitchell assumes that the metabolic nitrogen in feces is of the order of 0.23 g, or the protein equivalent is 1.4 g per 100 g of dry food consumed. If the dry matter in the fresh meat is 30 per cent, then the metabolic nitrogen in the feces is $0.3 \times 1.4 = 0.4$ per cent. The final net protein value is then $14.1 - 0.4 = 13.7$ per cent of the fresh meat. This is the maximum percentage of protein ($6.25 \times N$) in the food which is available for maintenance or productive purposes. The foregoing table is from Mitchell and Hamilton (p. 779). We added the last column on the right side of the table to represent the net protein value of the protein, which is the product of the "biological value" and the "true digestibility" of the protein. "True digestibility" is the difference between the fecal N (called metabolic N) on a low protein diet and the fecal N on the experimental diet.

The problem of evaluating the various categories of urinary and fecal nitrogen, together with the cogent literature^{138, 139, 140}, are discussed in Sections 13.1 and 14.9.

The protein needs in relation to body size in different species were previously discussed (Ch. 15), and the needs for adult man, about 70 g a day for a 70-kg person, are indicated in Table 20.1. To make this value concrete, one may note that per serving (100 g or 3½ oz), meat, poultry, or fish contains about 17 g protein, enough to supply a fourth of the day's need; a pint of milk contains about 16 g; 4 slices (100 g) whole-wheat bread contains about 10 g protein (white bread contains 8 to 9 g); an egg contains about 6.7 g protein. Per pound, meat, fish, or poultry contains 66 g protein; dry legumes and nuts 97 g; grain products 40 g; leafy vegetables 6 g; potatoes 8 g; dried fruits 13 g.

20.8. Notes on mineral relations in nutrition. The average mature human body contains the equivalent of about 5 per cent ash, equivalent to about 6 lb ash, which comes from and returns to the earth. The percentage composition of this ash is approximately: calcium 40, phosphorus 22, potassium 5, sulfur 4, chlorine 3, sodium 2, magnesium 0.7. According to Sherman¹⁴¹, the percentage composition of the average human body is approximately: nitrogen 3, calcium 2, phosphorus 1, potassium 0.35, sulfur 0.25, sodium 0.15, chlorine 0.15, magnesium 0.05, iron 0.004, manganese 0.0003, copper 0.00015, iodine 0.00004 and other trace elements, including zinc (see Sects. 6.4.2 and 6.6.IV for details). In an average 70-kg (155-lb) body this amounts to about 2.1 kg nitrogen, 1.4 kg calcium, 700 g phosphorus, 245 g potassium, 175 g sulfur, 105 g sodium, 105 g chlorine, 35 g magnesium, 2.8 g iron, 0.21 g manganese, 0.105 g copper, 0.028 g iodine.

From the structural viewpoint, the bony skeleton is composed mostly of calcium and phosphate; 99 per cent of the body calcium and 90 per cent of the phosphorus is in the skeleton. The mineral proportions in bone may be roughly represented by the formula $\text{CaCO}_3 \cdot 2 \text{ to } 3 \text{Ca}_3(\text{PO}_4)_2$, or more precisely¹⁴² $[\text{Ca}_{8.50}\text{Mg}_{0.25}\text{Na}_{0.19}] [(\text{PO}_4)_{5.07}(\text{CO}_3)_{1.24}](\text{H}_2\text{O})$.

From the catalytic viewpoint (Sect. 6.4.2), the minerals (including calcium and phosphorus) that function at trace levels serve as prosthetic groups, or coenzymes, or activators, as do vitamins, in electron-transfer enzyme systems. Some of these elements are associated with or constituents of, among others, iron in hemoglobin and cytochrome oxidases; magnesium in chlorophyll, carboxylases, phosphatases; manganese in arginase; copper in hemocyanin and many oxidases; calcium in some oxidases; zinc in carbonic anhydrase, in uricase, as carboxylase activator and possibly as catalyst for insulin storage in the pancreas (milk contains 0.5 mg zinc per liter); aluminum in a succino-oxidase system; and phosphates in phosphorylation. Many other trace elements must have similar functions because they are almost universally present, and their absence is associated with diseases similar to those due to vitamin deficiency. For instance, cobalt is necessary in traces, about 0.05 mg per day for sheep and 1 mg per day for cattle. Like excess copper, excess cobalt is toxic, causing the blood disease polycythemia. Minute traces of boron are essential, at least for plants, and it is universally found in milk and blood. Fluoride seems to be essential in minute traces, especially for healthy teeth; and as for copper, it is very toxic if taken in excess of about 1 mg per liter (1 ppm) water. Traces of arsenic are found in human blood.

As regards iron, 65 per cent of the body iron is in the blood, 30 per cent in the liver, bone marrow and spleen, and 5 per cent in other tissue. Liver is the richest animal dietary source of iron (20 to 80 ppm*) and also of copper (20 ppm). Egg yolk is even richer in iron (85 ppm). While the iron level in milk is low (2.5 ppm iron and 0.2 ppm copper), it is highly available. The blood-regenerating properties of foods and feeds are dependent not only on the content of iron, but also on the degree of its utilization. For instance¹⁴³, blood is rich in iron (37 mg per 100 cm blood), but only about 11 per cent of it is utilized; hence only 4 mg iron per 100 g blood is available. Heart muscle is poor in iron (15 mg per 100 g muscle), but as 90 per cent of it is utilized, 14 mg iron per 100 g muscle is available. Similarly, spinach is very rich in iron (38 ppm) but only 20 per cent of it is available; carrot is poor in iron (6 ppm), but 100 per cent of it is available. It thus appears that the available (rather than total) iron is 40 mg for 100 g liver, 15 for heart, 7 for skeletal muscle, and 4 for blood. Blood is richest in iron but poorest as a dietary iron food.

Liver, kidney, and gizzard have the highest overall blood-regenerating values, followed by egg and heart; of plant products, apricots, peaches, prunes, and apples stand high next to the liver-kidney category¹⁴⁴. Most leafy vegetables are relatively poor iron foods although rich in iron, partly because of its relative unavailability.

* ppm stands for parts per million, that is mg per kg.

¹⁴³ Sherman, W. C., *et al.*, *J. Biol. Chem.*, 107, 383 (1934); 119, 725 (1937).

¹⁴⁴ Robscheit-Robbins, F. S., *Physiol. Rev.*, 9, 666 (1929); *J. Am. Diet. Assn.*, 8, 387 (1932-33).

There is usually no lack of iron in natural foods, but if the soil is poor in iron, the foods may be likewise. In such cases of nutritional anemia, the diet is supplemented with iron, usually in the form of ferric ammonium citrate for humans and ferrous sulfate ("copperas") for animals¹⁴⁵, about half pound per 100 pounds feed. (The dosage for humans is about 1 g per day of ferrous sulfate or 5 g a day of ferric and ammonium citrate.)

The essential need of copper for iron utilization in hemoglobin building is known¹⁴⁶. One must be cautious, however, in feeding copper as it is toxic above a certain low level. Young women are said^{146a} to need 2.0 to 2.5 mg copper a day, an amount obtained from otherwise mediocre food. There is probably enough "impurity" copper in commercial iron preparations to meet all needs. In the "salt sick" regions of Florida, it is customary to add to 100 lbs common salt for livestock about 25 lbs red oxide of iron, 2 lbs "snow form" copper sulfate, and 1 oz cobalt chloride.

Blood regeneration is also dependent on many other factors, including hormones, of which the antipernicious anemia-factor in liver is one, and on vitamins and trace elements such as cobalt in ruminant iron utilization. Deficiency of cobalt causes "coast disease" in South Australia¹⁴⁷, "enzootic marasmus" in West Australia¹⁴⁸, "bush sickness" in New Zealand¹⁴⁹, "salt sickness", "hill sickness", and just plain sickness in Florida¹⁵⁰, cured by drenching the animals with 1 mg cobalt per day. "Bush sick soils" contain 0.12 per cent cobalt as contrasted to 0.61 per cent in healthy soil¹⁵¹.

As explained elsewhere (Sects. 20.2 and 21.2), milk is the best, and practically indispensable, source of calcium. Two large glasses a day supply all the needed calcium. In such countries as China where milk is not available, bones are consumed as such and in bone soups cooked in "sweet and sour" (with vinegar). The vinegar disintegrates the hard bone and renders its calcium available. It is customary for dairymen to keep bone meal before their dairy cattle at all times to supply the calcium for milk production. The bone meal is supplemented with other minerals, such as iron, copper, and cobalt, as required to meet the mineral deficiencies in the soil. The bone meal is also often supplemented with vitamin D in one of several forms to facilitate calcium absorption (Sect. 7.5).

When a soil is deficient in minerals, this is reflected in the composition of the plant. For example, in a recent survey, the calcium content in alfalfa

ranged from 0.5 to 5.0 per cent, and the iron content in cabbage ranged from 1 to 10 ppm, depending on the soil¹⁵². The composition of the plants in turn is reflected in the animals which consume them. This is one explanation for the geographical differences in size and vigor of plants and animals¹⁵³. Some authors¹⁵⁴ attribute the increase of many diseases, from hay fever to tooth decay and from sterility to grass tetany (grass tetany may be due, among other factors, to magnesium deficiency¹⁵⁵), to a decline in soil fertility. However, the minerals of commerce are inexpensive, and it is a simple matter to supplement table salt with the deficient minerals as is done now with iodine. As a result, goiter has been practically abolished. Tooth decay (in children) is greatly reduced by adding to the city water supply one part per million of fluoride¹⁵⁶ (or even by applying 2 per cent NaF solution to the crown surface directly¹⁵⁷). However, the mineral composition of the soil may influence the organic composition of the plant, for example its protein and vitamin¹⁵⁸ content; a regional agricultural experiment station was recently established in Ithaca, New York, to investigate the nutritional value of plants in relation to the composition of the soil.

To sum up, inorganic elements have important functions in catalytic processes and in structural elements. What was said about the effects of vitamin deficiency is applicable to mineral deficiency also, as minerals are prosthetic groups and coenzymes of various oxidation catalyst systems. The composition of the soil affects that of plants and animals, with consequent influence on human welfare.

In human diet, normally, only two minerals, calcium and iron, are likely to be deficient. The average adult need for calcium is about 0.7 g and for iron 12 mg. The best calcium food is milk, which furnishes about 0.56 g per pint, about $\frac{2}{3}$ of the day's need, followed by other dairy products—1 oz cheddar cheese furnishes 0.27 g—and by greens, such as turnip greens, mustard greens, collards, each of which furnish about 0.3 g calcium per serving of 100 g or 3½ oz. As previously noted, liver is the best source of iron, about 8 mg per 100-g serving, followed by other visceral organs, and by fruits, as peaches, prunes and apples. A serving of greens, such as turnip tops, beet greens, and chard, each furnishes about 3 mg iron; 100 g (4 slices) whole-wheat bread furnishes 3 mg, but white bread only 0.9 mg iron.

20.9. Note on energy relations in nutrition. Table 20.1 indicates the human dietary need for energy. Roughly speaking, a 70-kg mature person at rest requires about 30 Calories per kg body weight; at light work 40 Calories per kg; at moderate work 50 Calories per kg; at hard work 60 Calories per kg. Larger individuals require less energy per unit weight (Ch. 15).

A 100 g or 3½ oz serving of bread (4 slices) furnishes 250 to 300 Calories, meat 150 to 400 Calories (depending on fat content, ham is 500 Calories, lean beef heart 150 Calories, good beef loin 375 Calories). In terms of Calories per pound for broad categories, meats, fish, and poultry have a value of about 1100 Calories per pound; fresh eggs 635; milk 360; butter 3320, other fats 3900; potatoes 330, fresh and canned fruits (other than citrus) 290, dried fruits 1280.

As explained in Ch. 6 and Sects. 20.2 to 20.5, the degree of utilization of the energy depends on the balance between the nutrients and the level of dietary energy intake (Ch. 5) in relation to need; hence the given energy values of foods have such values only under certain conditions.

20.10. Summary and appendix. This chapter discusses selected topics in nutrition germane to the spirit of this book, including the following.

(1) Species differ in dietary dependence on vitamins and amino acids. Ruminants, such as cattle and sheep, are unique in not being dependent on dietary water-soluble vitamins; indeed, vitamin A (carotene) is the only one which often becomes limiting in this class of animals, especially as much of the carotene is destroyed in the rumen. Ruminants are also unique in being able to convert dietary non-amino nitrogen into amino acids and proteins. These peculiarities and their ability to consume roughage which cannot otherwise be utilized in the agricultural economy, and to convert

¹⁴⁹ Hamilton, J. W., and Hogan, A. G., *J. Nut.*, 27, 213 (1944).

¹⁵⁰ Sure, B., *Id.*, 26, 276 (1943).

it very efficiently into milk and (much less efficiently) meat, places the ruminant, especially the highly developed dairy cow, in a class by itself as a converter of feed into food. The simpler the alimentary canal, and the less the ability to handle bulky roughage, the greater the possibilities of developing dietary deficiencies.

(2) Species and individuals differ in "nutritional wisdom", in the spontaneous selection of foods that promote well being. In man, the "spontaneous" choice is perhaps modified by intelligence which is, however, confused by social conditioning factors. This confusion is, on the other hand, ameliorated by rapid accumulation of knowledge as to what constitutes an optimal diet, which is discussed at some length.

(3) Several methods are used for comparing the nutritional values of food combinations, among which the *ad libitum* and paired-feeding methods are discussed in detail, and briefer attention is given to the total life-history method.

(4) The nutrients are grouped into nitrogenous, energy-yielding, vitamin, and mineral. Foods and feeds vary in nutritional value because of differences in digestibility and difference in balance between nutrients, not only between these four categories of nutrients but also between the constituents, individual amino acids, vitamins, and minerals. The balance between the nutrients is not at a sharp point but in a broad zone, and wise dietary economics depend on the appreciation of the degree of freedom of movement within this zone.

(5) With the exception of vitamin A, which all species need, there are enormous species differences in reaction to a given vitamin deficiency, even if ruminants are omitted from consideration.

(6) Minerals, such as calcium and phosphorus compounds, function as structural elements; but these two, as well as all the essential trace elements, also act as catalysts in oxidation processes in the manner of vitamins. The lack of traces of cobalt in the soil, for example, was the limiting factor in the progress of the dairy and sheep industries in Australia and Florida; the discovery of the indispensable nature of cobalt changed the outlook for these industries and enlarged the perspective of the science of nutrition, substantiating the importance of "little things" in nutrition.

This chapter touched briefly on a few selected nutritional topics; it could be greatly expanded. The science of nutrition, as contrasted to the arts and instinct of feeding, is very new, very fertile, and is expanding very rapidly. The field of nutrition includes the identification of nutrients required by different species; their minimal and optimal consumption in relation to age (Ch. 14), to body size (Ch. 15), to climate (Ch. 11), to various functions (growth, reproduction, lactation, muscular work, fattening, and so on); nature of the participation and mechanism of action of each nutrient, especially of the catalysts (Ch. 6); consequence of dietary deficiencies and ex-

cesses (Chs. 5 and 18); nutrient balance (antagonisms and synergisms) and replacement; composition of foods with respect to nutrients and to other factors, such as bulk of a certain character and related factors in intestinal hygiene; influence of food processing (heating, milling, etc.) and of environmental factors (soil, temperature, light) on composition and nutritive value; neuro-psyche drives for each of the foods and the effects of various nutrient proportions in the diet on the neuro-psyche behavior, including nervous stability and mental activity, and so on. All these factors enter into the overall and long-range efficiency complex discussed in this book.

The following appendix presents data in tabular form for recommended nutrient allowances for man (Table 20.1); actual food consumption (Table 20.1a); composition of foods, presented in various forms (Table 20.1d); efficiency and economy with which various classes of food are produced (Table 20.2a and b).

Table 20.1. Recommended Dietary Allowances.
National Research Council, Circular 115, 1943

	Calories	Protein (g)	Calcium (g)	Iron (mg)	Vita- min A (I.U.)	Thia- min (B ₁) (mg)	Ribo- flavin (mg)	Niacin (Nico- tinic Acid) (mg)	Ascor- bic Acid (mg)	Vita- min D (I.U.)

¹ When liver is used add 25,000 I.U. Vitamin A and 14.6 mg. of riboflavin per pound of liver.

² Use this figure only when the combined weight of the lean pork cuts (viz., fresh and cured ham, pork loin and chops, Boston butt, and shoulder) is 15% or more of the weight of the meat group. When the combined weight is less than 15% compute the thiamine thus: (wt, in lbs, of lean pork cuts \times 5.9) plus (wt in lbs, of all other meat \times 1.0). This gives the quantity of thiamine in milligrams in the entire group.

³ Values based on new enrichment levels effective October 1, 1943. When enriched flour and bread are not used, count thiamine in the entire group as only 0.59 mg per pound, riboflavin 0.29 mg per pound, nicotinic acid 4.2 mg per pound, and iron 5.5 mg per pound (based on "straight" flour); no changes need be made in other nutrients.

Table 20.1c. The monetary cost of nutrients per day of several foods.

The first column under each nutrient gives the cost in cents for the day's recommended allowance for the average adult, not counting the value of other nutrients in the food (as cost of 70 gm protein recommended for the average 70-kg man, not counting other nutrients in the food); the second column indicates the percentage of the daily requirement supplied by a serving (weights which are given in the second column from the left). Thus 244 gm (or 8.6 oz or $\frac{1}{2}$ pint) milk supplies 40% of the daily calcium requirements, 12% of the protein requirement, 20% of the riboflavin requirement, and so on. Modified from Barbara Kennedy, Cornell Univ. Agr. Exp. Sta. Bull. 774, 1941.

Food	Weight per serving "as purchased," g	Retail price cents/lb	Protein		Calcium		Iron		Vitamin A		Thiamine		Riboflavin		Ascorbic acid

Pub. 275, 1937. Booher, L. E., et al., "Vitamin Values of Foods", Id., Circ. 638, 1942. Hewston, E. M., and Marsh, R. L., "Vitamin Values of Foods", Id., Misc. Pub. 505, 1942. Munsell, H. E., "The Vitamin A, Vitamin B, Vitamin C, and Riboflavin Content of Common Foods", *Milbank Memorial Fund Quarterly*, 21, 102 (1943). Current (1943-44) issues of the *Journal American Dietetic Association*. Fixsen, M. A. B., "Vitamins in Human Foods", *Nut. Abst. Rev.*, 7, 8, 23, (1937-38); 8, 281 (1938-39); 9, 295 (1939-40).

² Standard Brands Circular (1944) cites the following values per 100 gm of its dry brewers yeast: water 4.1 g; protein 50 g; carbohydrate 33 g; fat 5.8 g; Ca 70 mg; P 161 mg; Fe 17 mg; Cu 2.1 mg; Zn 12.5 mg; Mg 270 mg; thiamine 50000 to 60000 mcg; riboflavin 7000 mcg; nicotinic acid 50 to 70 mg; pyridoxin 2.5 to 5 mg; pantothenic acid 10 to 60 mg.

³ Kohler, see next table. The values are on moisture-free basis.

⁴ O'Malley, C. M., and Gross, A. M., Am. Dry Milk Institute, Letter Nov. 1943. Also ash 8.16% as contrasted to 5.85% in whole dry milk.

⁵ Burkholder, P. R., [Science, 98, 188 (1943)] cites the following vitamin values for edible varieties of mature soybeans, mcg/gm dry matter: thiamine 9.0, riboflavin 2.3, niacin 20, pyridoxine 6.4, biotin 0.61, pantothen 12; for green or immature soybean, thiamine 6.4, riboflavin 3.5, niacin 40, pyridoxine 3.5, biotin 0.54, pantothen 12, ascorbic acid 0.21 mg/gm dry matter.

Table 20.1c. Composition of Dehydrated (at 80°C) Young (3-6 Weeks after Planting) Cereal Grass on Moisture-Free Basis

Data kindly furnished by George O. Kohler through courtesy of W. R. Graham, Jr., Basis of charts 2 and 3, *J. Biol. Chem.*, 152, 215 (1944).

Age from planting (days) ¹	Vitamin B ₁ (thia- mine) (mcg/g)	Vitamin B ₂ (ribo- flavin) (mcg/g)	Vitamin C (as- corbic acid) (mg/g)	Caro- tene ² (mcg/g)	Biotin (mcg/g)	Panto- thenic Acid (mcg/g)	Nia- cin (mcg/g)	<i>L. casei</i> growth factor ³ (mcg/g)	Pro- tein (per cent)	Fat (pet. ether extract) (per cent)	Fiber (per cent)	Chloro- phyll total (mg/g)	Solids in fresh grass (per cent)
24	12.9	26.8	6.41	0.549	.181	13.7	92.5	17.0	25.1	7.2	16.1	8.35	11.0

45	6.5	14.6	3.69	0.344	.173	16.8	52.9	6.4	16.3	6.8	25.7	5.16	16.0

¹ The vitamin, protein, and fat content of the leaves is near maximum at the jointing stage. Most of Dr. Kohler's plants jointed by the 27th day (about 13½ inches long). The first grain heads appeared on the 39th day. The *L. casei* growth-factor data are not claimed to be (by Dr. Graham) "as absolutely sound".

² *L. casei* growth factor, or "Norit eluate factor", is presumably identical with folic acid, vitamin B₉ (Hogan's anti-anemia vitamin).

³ The carotene values appear high, but not unreasonable. Thus Vernon Booth (*Chemistry and Industry*, 61, 255, 1942) quotes in mg per 100 gm fresh mixed grasses in June, carotene 6.0, thiamine 0.11, riboflavin 0.13, nicotinic acid 0.7, ascorbic acid 100. L. A. Moore and R. Ely (*Industrial and Engineering Chemistry*, 13, 600, 1941) quotes mcg carotene per gram fresh green material, June grass 155, clover 200, alfalfa leaf 100, carrot root 105. But for hay, alfalfa 2 to 25, soybean 50 to 80; for dehydrated alfalfa leaf about 80.

Table 20.2a. Relative Efficiency of Production of Human Food Nutrients from Livestock

Christensen, R. P., "Using resources to meet food needs," U. S. Dept. Agr., Bur. Agr. Econ., 1943

	Calories (1000's)	Protein (lb)	Calcium (g)	Phos- phorus (g)	Iron (mg)	Vitamin A (1000 I.U.)	Thia- mine (mg)	Ribo- flavin (mg)	Niacin (mg)

Chapter 21

Milk: Nutritional, Social, and Physiological Aspects

Thou shalt have milk for thy food, for the food of thy household, and for the food of thy maidens. *King Solomon*

Milk is the nearest thing we possess to a perfect and complete food, and no other single food can be employed as a substitute. *Hariette Chick*

The production of milk constitutes the most economic method of converting feeding stuffs into animal products and the maintenance of milk supply is the most important object of war-time husbandry. *Norman C. Wright*

21.1: Introduction. The milk problem has surprisingly complex inter-relations: energetic efficiency (Chs. 1, 2, 3, 21, 22), endocrinologic (Ch. 7), seasonal (Ch. 8), temperature (Ch. 11), nutritional and medical (Chs. 4, 5, 6, 20, 21, 22), time relations and aging (Chs. 16, 18, 19), evolutionary, organismic and homeostatic (Chs. 7 and 10), form-function (Ch. 17), soil fertility and national stability (Ch. 25), and so on.

Milk production has been said to be the backbone of American agriculture and milk consumption the keystone of American nutrition. The proverbial vigor of the pastoral peoples is undoubtedly associated with their high milk consumption, and Americans match them in vigor.

There is one milking cow for five persons in the U. S. A. At the current rate of milk production (5000 lbs milk per cow per year), one quart is produced per capita per day. Of this one quart about half is consumed in fluid form; the remainder is used for producing butter (about 20 lbs of 4 per cent-fat milk for one pound of butter), cheese (about 10 lbs milk per lb cheese), ice cream (over two quarts of milk for one quart of ice cream), evaporated and condensed milk (2.2 lbs milk per lb evaporated milk), powdered milk (8 lbs milk per lb powdered milk), malted milk (2.6 lbs milk per lb malted milk), and so on. The by-products from the production of butter ("defatted milk" or skim milk), cheese (whey), and so on, are utilized as food for man, feed for animals and for the manufacture of various products, such as casein, lactose, confections, vinegar, sizing, various plastics for buttons, "wool", etc.

The importance of milk is indicated by the fact that about one-fifth of the average farmer's cash income is derived from the sale of milk and one-fifth of the average consumer's food dollar is expended for milk and dairy products. (The 1941 American per capita consumption was 164 quarts fluid milk, 18 lbs

butter, 6 lbs cheese, 16 lbs evaporated milk, 2 gals ice cream, and considerable amounts of powdered milk). While the dairy industry is gigantic in the aggregate¹, the average dairy farm is small, typically a single-family enterprise. Half the country's dairy cows are in herds of 8 cows or less, and three-fourths are in herds of 15 or less (only 5 per cent of the cows are in herds of 30 to 50 cows, 2 per cent in herds of 50 to 75, and 1 per cent in herds of over 75 cows). Dairy farming is thus one of the few remaining stable family business enterprises; indeed, it is a way of living as well as a way of making a living, with corresponding far-reaching implications for national stability (Chs. 10, 16, 25). It is generally agreed that national welfare (health, soil fertility, population stability) demands that everything should be done to maintain a prosperous dairy industry.

While the production of pork, beef, egg, requires less human labor in proportion to food yield than the production of milk² the dairy cow is far more efficient in converting cattle feed into human food than are other farm animals in converting feed into meat or egg. The energetic efficiency of milk production in superior dairy cattle is 33 per cent, contrasted to about half this level, 17 per cent, for egg production in comparable superior fowls, and 5 to 15 per cent for meat production (Chs. 1, 3, 22, 23). The energetic efficiency of milk production is so much greater that in spite of the greater labor cost of milk production the current price of egg and meat is about \$1.10 per pound of dry matter, whereas the price of whole fluid milk comes to about 50 cents per lb of dry matter and of non-fat dry milk (dry skim milk), only 14 cents per lb. Moreover, methods are being developed to reduce the human labor involved for milk production by greater use of better machines and by the use of larger animals of higher dairy merit (Ch. 22).

Furthermore, cattle consume roughage which swine and poultry cannot consume and, unlike non-ruminants, synthesize by way of rumen micro-organisms complete nutrient proteins from incomplete feed protein and virtually all the B vitamins (Ch. 20). The milk nutrients are thus, in part, obtained in the nature of a windfall, from material which is otherwise nutritionally useless.

Dairy cattle now consume³ 91 per cent of all the silage consumed by farm animals, 53 per cent of the hay, 38 per cent of the other dry roughages, and 38 per cent of the

¹ U. S. consumers spend over 3½ billion dollars a year for milk and dairy products, and the dairy industry employs (1938) "four times as many people as the railroad industry, fifteen times as many as the telephone industry, nineteen times as many as the automobile industry, and one out of every 15 U. S. families is dependent on milk for a living." See Table 21.7.

² The annual labor of milking and caring for a cow producing 5000 lbs milk, and growing her feed, is estimated to be 160 hours; for producing a 400-lb beef steer, 32 hours; for raising a 5-pig litter to 125 lbs per pig, 75 hours. On this basis, the food-energy return index per man-hour is 100 for the milk, 219 for the hog, and 305 for the steer; the food-protein return per man-hour is 100 for milk, 98 for hogs, and 112 for beef.—O. H. Brownlee, "Putting Dairying on a War Footing," Iowa State College, 1943.

³ Jennings, R. D., U. S. D. Agr. Circular 670, 1943.

pasture. These are feeds which cannot be used by man or even by swine or poultry. Dairy cattle consume only 19 per cent of the grain and other concentrate feeds. Swine, however, consume 48 per cent of all the corn or 35 per cent of all the concentrate feeds and except for about 2 per cent pasture, no roughage. Poultry consume 21 per cent of all concentrate feeds and for about 1 per cent pasture, no roughage. Speaking very generally—the feed units are not really equivalent for different farm animals—dairy cattle consume 34 per cent of all the feed consumed by farm livestock, beef cattle 20 per cent, sheep and goats 7 per cent, horses and mules 14 per cent, swine 15 per cent, poultry 9 per cent. These figures give a rough idea of the relative magnitude of the dairy industry from the viewpoint of use of raw material.

21.2: Nutritional importance of milk. Unlike other foods which he had to learn to consume, man, in common with other mammals, is a born milk consumer. Milk was evolved through the ages specifically for the nutrition of infant mammals, for bridging the gap between the dependent intrauterine and the independent adult life (Sect. 7.2). Milk from all species contains the same nutrients, although in different proportions. Finding milk good, man domesticated convenient mammals for furnishing him with milk throughout his life.

Having been developed for nourishing rapidly growing yet delicate and toothless infants, milk has unique physical and nutritional properties. Milk is bland, soothing, fluid, yet highly nourishing; hence its use as food during “melancholy”⁴ and other disturbances, especially digestive, such as ulcer, for which milk is often used as a virtually exclusive diet⁵.

Milk is commonly thought of as a “drink,” but this must not lead one to the mistaken idea that fluid milk has less solids than some “solid” foods. Indeed, the opposite is frequently true. Thus, whereas the solid content in fluid milk is about 13 per cent, that in turnips is only 9 per cent, in tomatoes 6 per cent, in lettuce 5 per cent. Milk is, of course, easily made “solid” by treating it with rennet or by simple souring, both of which may be followed by “baking.” The writer recalls the pleasant flavors and tastes of many sour-milk dishes partaken while visiting in the Balkans, especially in Belgrade, where “Bulgaricus Milk,” made famous by Metchnikoff as a life prolonger, is so widely used by all classes of society. It is, of course, the nutrients in milk rather than the bacteria that prolong life (see, however, Rettger³⁷ below). Bulgaricus and other types of milk-souring destroy dangerous bacteria, thus making the milk safe as food. This is the major (even if unconscious) reason for the use of soured (or boiled) milk in much of Europe where hygienic conditions are not satisfactory and bovine tuberculosis is very common.

The nutritional importance of milk is indicated by the fact that a quart of cow's milk a day furnishes (Table 21.1) an average man (of 70 kg or 154 lbs) approximately all the needed fat, calcium, phosphorus, riboflavin, one-half of the needed protein, one-fourth of the needed energy, over one-third of the vitamin A, one-fifth of the thiamine and ascorbic acid, considerable amounts

⁴ “Milk is especially good for them which be oppressed with melancholy, a common calamity of students.”—Thomas Cogan, 1584.

⁵ Shay, H., *Jour. Am. Med. Assoc.*, 120, 740 (1942).

of nicotinic acid and choline, and other factors, and, with the exception of iron, copper, manganese and magnesium, which are low in milk, all the needed minerals. (The protein in a quart of milk is roughly equivalent to that in 5 ounces of meat or fish, or 5 large eggs, or 4 ounces of American cheese, or 16 slices of bread. The energy of a quart of milk is roughly equivalent to that in $\frac{3}{4}$ lb of meat, or 8 eggs, or 2 lbs of potatoes.)

These estimates do not fully indicate the contribution of milk to the average diet because of the unique *supplementary* value of milk to other foods (Sect. 20.4). For example, when growing pigs are fed only cereal, about 30 per cent of the cereal protein is utilized for growth; but if milk is added to the diet (liquid milk equal in weight to the cereal weight) 60 per cent of the protein is utilized for growth⁶ because of the supplementary effect of the protein and other constituents of milk.

Dramatic results of broad social significance were reported on the supplementary value of milk on growth of children, especially those by Dr. Corry Mann⁷. His boys were receiving a diet rated as adequate, but Dr. Mann wanted to see what an extra glass of milk at meals (a pint per day) would do. Records were kept of half of the group on their usual diet, and of an equal number who received the milk supplement. The result was that while the "control" boys gained 4 lbs in weight and 1.8 inches in height, the milk-supplemented group gained 7 lbs and 2.6 inches. "The casual visitor would never fail to recognize the boys receiving the extra milk," said Dr. Mann; "they were obviously more fit."

The spectacular growth-accelerating effect of milk on weight and especially on height (skeleton growth, see Fig. 21.1b) is perhaps due largely to the richness and availability of calcium in milk. In Mann's experiments the addition of casein equivalent to that given in milk and margarine equivalent to the butter-fat in the milk did not increase the height as did whole milk. Leighton and Clark⁷ found that *skim milk increased growth in height as much as whole milk*. These observations lead to the conclusion that the calcium in milk is a major factor in increased growth of the skeleton. Ordinary diets are more often deficient in calcium than in any other nutrient, and are thus made good by milk.

These observations on the remarkable influence of *skim milk* supplement on growth suggest the need of elucidating a current problem in the dairy industry.

As previously noted, there is enough milk produced in the United States to furnish a quart per capita per day, the optimal level of milk intake. Half of this milk, however, is used for manufacturing butter (about 18 lbs per capita per year) and cheese (about 6 lbs per capita per year). The popularity

Fig. 21.1a

Fig. 21.1b

Fig. 21.1a to c. Plotted from data by B. W. Fairbanks, *Cereal Chem.*, 15, 169 (1938). Three groups of 50-gm. rats were placed for 77 days on three kinds of bread diets: 1, ordinary white bread; 2, white bread containing 6 per cent dry milk; 3, white bread containing 12 per cent dry milk. In these 77 days the rats in group 1, gained 35 gm. at a food cost of 25 gm. bread per gm. body gain; group 2, gained 110 gm. at a cost of 6.6 gm. bread per gm. body gain; group 3, gained 164 gm. at a cost of 5.2 gm. bread per gm. gain. While the larger animals had a higher maintenance cost (because of their larger size), yet their gains were more economical.

Fig. 21.1c.
See legend on page 796.

of butter is, of course, due to its high nutritive value, its very tasty flavor, ease of its manufacture from cream and ease of preservation. The advent of the mechanical cream separator and the Babcock tester made it easy for the farmer to separate cream from milk to any fat percentage, and for the butter-maker to pick up the cream for butter manufacture. The skim milk was fed to the swine and poultry, for, as previously noted, milk, even skim milk, is an excellent supplement to cereals normally fed to these animals.

But it is also good for man to supplement his cereal with milk, even skim milk; and as long as there is not enough of a given food for man, it is, usually, wasteful to feed this food to livestock. For example, per unit dry matter, milk is nutritionally equivalent to meat; yet when fed to animals only about ten per cent of the milk solids is recovered in the form of meat solids⁸ (Ch.3). Thus it is estimated that about 50 billion pounds of skim milk⁹ (about 4 billion pounds non-fat dry-milk solids) perhaps 40 per cent of the total milk solids produced in the United States, said to be equivalent to the protein in 200 million beef steers¹⁰, is diverted from human use, and 90 per cent of it is wasted as far as human nutrition is concerned. (There are, of course, exceptions, as when a little skim milk may be the limiting factor in a ration for chickens in egg production.)

More specifically, Krauss¹¹ reported that if United States milk production were completely utilized as human food, the non-fat part of the milk would satisfy the protein needs of 67 million persons, the riboflavin needs of 130 million persons, the calcium needs of 165 million persons; but that according to the present practice of feeding the skim milk and whey to livestock, etc., only half of these nutrients are utilized for human consumption. This huge waste of food is due to a serious misunderstanding about the nutritive value of defatted or skim milk. Let us, therefore, discuss this problem briefly.

⁸ Abbott, J. S., *Am. J. Public Health*, 30, 237 (1940).

⁹ "Consumers' Guide," U. S. D. Agr., July, 1939.

¹⁰ Rose, W. C., Jones, D. B., Morse, W. J., and Pollock, R. C., "The Nation's Protein Supply," Nat. Research Council Reprint and Circular Series, No. 114, Aug. 1942.

¹¹ This discussion is based mostly on Krauss, W. E., Address American Dry Milk Institute, April 14, 1943; Reed, O. E., Address National Dairy Council, June 28, 1943.

The composition of whole milk is given in Table 21.1 in the form of a comparison between the nutritional needs of an average adult person and the nutrients furnished in a quart of average market milk (slightly modified from Krauss¹¹).

Table 21.1 shows that a quart of average milk (2.15 lbs or 4 glasses of 8 fluid ounces each) supplies to an average moderately active man approximately the following percentages of the nutrient standard: 150 per cent of the calcium, 70 per cent of the riboflavin and phosphorus, 50 per cent of the protein, 40 per cent of the vitamin A¹², 25 per cent of the ascorbic acid¹³, 20 per cent of the calories and thiamine, 5 to 10 per cent of the iron, nicotinic acid, and vitamin D¹².

The milk energy is seen (Table 21.1) to be equally divided between fat, 330 Calories (37 gm fat per quart) and non-fat, 330 Calories (49 gm lactose and 34 gm protein per quart). (The energy value of whey is about 270 Cal per quart or per kg.) The milk *fat* thus supplies half the milk energy, the vitamins A and D, and much of the flavor; the *non-fat* part of the milk, the *skim milk*, supplies the other half of the energy, the proteins of high biological value, calcium, riboflavin, phosphorus, iron, ascorbic acid, thiamine, nicotinic acid, and apparently some unknown growth factors (Reed). It is thus clear that in evaluating milk as a food, at least as much value should be placed on the non-fat as on the fat portion.

A slow transition may be taking place in the dairy industry as a result of the war and its associated world-wide food shortage¹⁴. Ways will, no doubt, be found to save the skim milk, buttermilk, and whey for the human dietary.

¹² The vitamin-A value of milk varies with the carotene content of the feed. Fresh pasture yields milk highest in vitamin A content, followed by well preserved silage, then by hay, especially if dried by rapid-drying methods.—Hilton, J. H., *et al.*, *J. Dairy Sci.*, **16**, 355 (1935). For the influence of feeding high vitamin A shark-liver oil on the vitamin A in milk, see Jensen, C., *et al.*, *J. Dairy Sci.*, **25**, 1931 (1943). Likewise, the vitamin D of milk varies with the vitamin D content in the feed as well as with *sunshine*.

¹³ There is a large literature on the ascorbic acid content of milk. The ascorbic content in cow's milk is about one-sixth and the iron content about one-third of that in woman's milk but the riboflavin content of cow's milk is about five-fold that of woman's milk. Heating in copper dishes destroys ascorbic acid. To save ascorbic acid in sterilization, heat the milk to the boiling point *very* quickly (to destroy ascorbic acid oxidase) then boil for three minutes. The ascorbic acid content of unpasteurized milk ranged from 17 to 37 mg, average 26 mg/liter, for individual cows and 13 to 19 mg/liter in plant composites before pasteurization and 16 to 17 mg/liter after pasteurization. [C. H. Whitnah, *et al.*, *J. Dairy Sci.*, **19**, 373 (1936); **20**, 9 (1937)]. Other reports: 20 mg ascorbic acid/liter [P. F. Sharp, *Science*, **84**, 461 (1936)]; mixed milk before pasteurization ranged month to month from 14–22 (average 17.3 mg/liter) and after pasteurization 7.8–19.0 mg/liter [A. H. Holmes, *J. Am. Diet. Assn.*, **15**, 363 (1939)]. Some authors claim an ascorbic acid peak for summer milk, others for winter milk, yet the character of the cow's feed does not influence the ascorbic acid content in milk [Holmes, *J. Nut.*, **17**, 187 (1939); **26**, 337 (1943)]. The ascorbic content of human milk varies with the diet, but it is about 60 mg/qt. [King, C. G., *et al.*, *J. Nut.*, **11**, 599 (1936)]. The reports vary similarly for the other vitamins. Borsook suggested that milk should be enriched with crystalline thiamine as it is now frequently enriched with vitamin D.

¹⁴ The food shortage referred to applies to most of Asia and Europe but not to the United States, where malnutrition is due to ignorance and economic factors rather than to national lack of food as such. Indeed, the 1942 agricultural production schedule supplies protein adequate to feed 183 million persons (furnishing 81 lbs protein per capita per year or 73 gm per capita per day), whereas there are only 134 million persons in the United States. Rose, W. C., *et al.*¹⁰

Instead of separating the milk on the farm and feeding the skim milk to livestock, the creameries and cheese factories may take the whole milk and develop facilities for drying the skim milk, buttermilk, and whey¹⁵. The dry products may be sold in the form of capsules, wafers, or powder, perhaps variously flavored, on grocery shelves¹⁶, in jars, cartons, and air-tight, moisture-proof envelopes. The packages could contain $4\frac{1}{2}$ ounces (127 gm) solid whole milk, each equivalent to a quart of fluid whole milk, or the envelopes could contain a fourth of this, equivalent to a large glass of milk, or multiples of these amounts. When used for soups and baking, milk powder is said to yield products superior to fluid milk, since it is uncomplicated by the water in the milk. The recently developed food-compression machinery may be used for tableting milk solids, whole or defatted, to be consumed direct, as the very hard cheese in some parts of eastern Europe is consumed.

The organismic theory (Ch. 10) suggests that it would be better to consume whole milk than any of its parts, because it is probable that the various milk constituents supplement one another nutritionally. A given amount of whole milk has a higher physiologic energy value than the sum of its constituents taken separately at different times. The fat in the milk *supplements* the protein and the sugar in the milk. "It seems that nature has put lactose and milk fat together as an optimum combination for the young animal¹⁷." "Lactose has an as yet unknown effect on intestinal conditions which is counteracted by butterfat but not by corn oil." "Fortified oleomargarine did not give growth equal to butterfat when lactose was the sole carbohydrate in the diet. . . . Fortified oleomargarine gave growth equal to butterfat over a period of 6 weeks when . . . a mixture of carbohydrate (sucrose, starch, dextrine, lactose) was incorporated."

It would, then, seem best to consume the recommended or available quart of milk per capita per day in the form of whole milk, fluid or evaporated, as a bread "spread" made by evaporating milk to the consistency of butter, whole-milk cheese (including the whey solids¹⁸), or best used in bread making¹⁹ as milk bread, and in soups²⁰, puddings, cakes, cookies, or in the form of a beverage, even as reconstituted milk²¹.

¹⁵ This is not a novel idea. See Eckles, C. H., *et al.*, "Milk and its products," p. 201.

¹⁶ Since the above was written, Merrill O. Maughan (American Dry Milk Institute) kindly sent me an $8\frac{1}{2}$ -oz package of powdered whole milk, equivalent to the solids in 2 qts fresh milk, which is being marketed "experimentally" in some localities for about 26 cents a package (equivalent to 13 cents a quart fluid milk). It is apparently less expensive to dehydrate, package, and market dry milk from grocery shelves than to process and market fresh milk. Moreover, the powdered milk keeps for months. The package had the following inscriptions: " $8\frac{1}{2}$ ozs net wgt, just add water . . . makes 2 quarts of fine fluid milk. . . . For best results use within sixty days of purchase." The given analysis: 27% butterfat, 26.8% protein, 38.1% milk sugar, 5.88% ash, 2.25% moisture, 142 Cal per ounce (about 5 Cal/gm). The reconstituted milk has a slightly cooked taste somewhat similar to that of evaporated milk.

¹⁷ Hart, E. B., Elvehjem, C. A., *et al.*, *J. Dairy Sci.*, **26**, 429 (1943); *Science*, **93**, 499 (1943); *J. Nut.*, **26**, 601 (1943).

¹⁸ Velveta cheese contains some of the whey solids. The composition of this cheese [as reported in the *Jour. Am. Med. Assn.*, **120**, 24 (1942)]: moisture, 43.1%; Calories per ounce, 90; fat, 23.4%; protein, 18.4%; carbohydrates, 10.1% (8.4% lactose); ash, 5.3%; calcium, 0.61%; phosphorus, 0.82%; salt, 1.8%; lactic acid, 1.2%.

¹⁹ Cf. Mitchell, H. H., *et al.*, *Bakers' Weekly*, **114**, 27 (1942); *J. Nut.*, **25**, 585 (1943).

²⁰ The M.I.T. in cooperation with the Rockefeller Foundation and the Kellogg Foundation developed a dehydrated milk soup containing 10% milk solids. A cup of this soup supplies the daily needs of all the known vitamins and minerals.

²¹ "Reconstituted milk," *Nut. Rev.*, **1**, 70 (1943).

While there can be no substitute for whole milk or for skim milk, claims are being advanced by the margarine industry that oleomargarine fortified with vitamins A and D to the butter level²², flavored with diacetyl or related butter flavor, and colored to the butter level with carotene may be acceptable to *adult* consumers who cannot afford butter. The question of unsaturated fatty acids of the linoleic acid type does not, perhaps, enter the problem, since most vegetable fats are as rich in this type of fatty acid as butter; nor, perhaps, does the question of "digestibility" (in adults).²³ There are, however, short-chain fatty acids (Table 21.2) and other substances in butter not present in other fats, and butterfat stimulates growth in young rats²⁴, ²⁵ and calves²⁶. As previously noted, however, the superior growth on butterfat in milk over that on vegetable oil in skim milk may be due to the supplementary effect of milk sugar on butterfat¹⁷. Milk fat seems to go best with milk sugar and vegetable fat with vegetable sugar. If butterfat goes best with the other milk solids, it is safe to predict that a new butter "substitute" will be developed in due time by the enterprising American dairy manufacturers, namely, whole milk evaporated to the consistency of butter, properly flavored, and advertised for use as a "spread" in butter fashion.

The butter-margarine problem is now receiving much attention basically because of the growth of the vegetable-oil industry and technological advances in margarine and vitamin A production. No one argues against butter. The following statement is generally accepted. "Our nation has grown up with butter on its bread. Butter was eaten for its taste long before there was any knowledge of nutrition. We like it on our hot cakes and in countless other ways for its flavor alone. Butter will always be in demand because of its flavor and palatability. These characteristics are not duplicated by any other fat" (Reed). But the margarine industry is pushing its product; and the broader national problem is how to avoid wasting the precious nutrients in skim milk and buttermilk produced in buttermaking. (O. E. Reed, Chief of the Federal Bureau of Dairy Industry, phrased this problem, thus: "Our dairy industry is not operating on the most efficient basis for our national nutrition—we skim the cream from a lot of milk and we use only the cream or the fat.") The outcome of this controversy between two industries is uncertain, but it would seem wise for the dairy industry to develop profitable whole-milk "spreads"²⁷ (by the simple device of evaporating whole

²² The vitamin A content of butter is between 5000 and 20000 I.U., average 15000 I.U. per pound [Dornbush, A. C., *et al.*, *Jour. Am. Med. Assn.*, **114**, 1748 (1940)]. The vitamin D content of butter is 50 to 500 I.U. per pound [Wilkinson, H., *Analyst*, **64**, 17 (1939)]. At the rate of 17 lbs butter consumption per year, the vitamin A furnished by butter is 600 to 700 I.U./day.

²³ For a review of the butter versus oleomargarine problem in 1942, see Council on Food and Nutrition, *Jour. Am. Med. Assn.*, **119**, 1425 (1942); **118**, 1469 (1942); **120**, 168 (1944).

²⁴ Hart, E. B., Elvehjem, C. A., *et al.*, *J. Biol. Chem.*, **122**, 381 (1938); *J. Dairy Sci.*, **23**, 181, 1201, 1205 (1940); **24**, 1027 (1941).

²⁵ Deuel, H. J., Jr., *Science*, **98**, 139 (1943), published evidence to the effect that the superior growth on milk fat is due to its superior flavor which caused the rats to consume more of the natural milk, and that flavoring the vegetable oil abolished the difference in growth rate. The problem is evidently still in the controversial stage. See also Deuel, *et al.*, *J. Nut.*, **27**, 107, 335, 339 (1944). The superior flavoring, diacetyl, referred to by Deuel is, however, not that of natural milk fat as consumed by infants (rats or other species), but is bacteriologically developed by buttermakers.

²⁶ Gullickson, T. W., *et al.*, *J. Dairy Sci.*, **22**, 471 (1939); **25**, 117 (1942).

²⁷ Grateful acknowledgments are made to all the author's (Dairy Department) colleagues for stimulating discussions and for especially valuable suggestions by E. R. Garrison and W. H. E. Reid. Since the above was written, K. G. Weckel, University of Wisconsin, assigned to the Wisconsin Alumni Foundation formula for a "dairy spread" containing 56% moisture, 26% butterfat, 16% non-fat milk solids, 1% salt,

milk to the consistency of butter, perhaps adding "binder" and flavoring, and add further to tastefulness of the product by proper publicity) and whole-milk cheeses (including whey solids).

The historical aspect of the nutritional importance of butterfat is generally known. Vitamin A was first discovered in milk fat²⁸, and the first severe cases of clinical xerophthalmia were described in children fed defatted milk²⁹: "The eye-sight of the children was sold abroad with the butter³⁰."

Milk fat is characterized³¹ by a high content (7 per cent) of volatile fatty acids, mainly butyric and caproic, with small amounts of caprylic and capric, and related acids. This is indicated by Table 21.2^{32, 33}. Vegetable fats and blood lipoids do not appear to contain fatty acids with less than 12 or 14 carbons. These short-chain fatty acids are apparently synthesized by the mammary gland, as there are none in blood.

The composition of milk fat varies with season, perhaps due to seasonal differences in the feed and also to temperature³⁴. The summer (pasture) milk is richer in oleic acid, poorer in butyric and stearic, but the palmitic remains constant. This may, perhaps, contribute to the differences in nutritive value of summer and winter milks.

The phospholipids (about 0.05 per cent lecithin in average milk, 0.2 per cent in cream, 0.016 per cent in skim milk, 0.13 per cent in buttermilk, 0.07 per cent cephalin in milk) are not definitely related to the amount of fat. Cow's milk contains twice as much phospholipid and four times as much phosphorus as human milk. The cholesterol content of cow's milk is about 0.02 per cent and of butter oil 0.3 per cent; 18 per cent of the milk cholesterol is associated with the lactalbumin rather than with the fat.

The short fatty acid and other milk-fat peculiarities may or may not be of nutritional significance. There are no experimental data on this question. It seems unreasonable, however, to suppose that the mammary glands of all mammals would evolve mechanisms for the synthesis of these short-chain fatty acids (see table below) without serving some need.

As previously noted, fluid (market) milk contains about 13 per cent solids; hence milk at 13 cents a quart is equivalent to one cent per one per cent solids per quart. Assuming that a quart of milk contains 4.5 ounces (127 gm) of solids, then at 13 cents a quart, the milk solids come to 2.9 cents per ounce (28.3 gm) or 46 cents a pound (453.6 gm).

The market price of butterfat is about 50 cents a pound, and it has been suggested³⁵ that milk sugar (lactose) is worth no more than store sugar (sucrose), *i.e.*, 5 cents a pound. This gives the milk protein and minerals a monetary value of one dollar a pound. (*Note:* Meat protein is \$1.00 a pound when meat is 20 cents a pound; cheese protein is 90 cents a pound when cheese is 30 cents a pound; egg protein is 75 cents a pound when egg is 30 cents a pound; bean protein is 13 cents a pound when beans are 10 cents a pound; white-flour protein is 10 cents a pound when white flour is 6 cents a pound³⁶.)

The above type of computation seems unfair because it omits the vitamins, trace elements, and unknown factors in milk, the optimal calcium-to-phos-

9000 units per pound vitamin A from fish-liver oil, 3200 units per pound vitamin D from irradiated ergosterol, also cultured buttermilk flavor and lactic acid. The making of the spread involves the use of a vacuum pan, pasteurizer, and homogenizer.

phorus ratio³⁶, and the unique properties of milk sugar." Unlike sucrose, lactose passes the ileo-cecal valve and forms in the intestine an exceptionally favorable medium for the growth of *Bacillus acidophilus*³⁷ and related acid producers, thereby inhibiting protein putrefaction. By thus maintaining an acid reaction in the intestine, lactose, moreover, favors maximum calcium and phosphorus utilization (at least in the rat). It is known that (in the rat) the ricket-producing properties of some diets are repressed by supplementing with lactose³⁸. The greater anti-rachitic value of woman's milk as compared to cow's milk is attributed to the higher lactose content of the former. Finally, lactose furnishes an important building stone, galactose (1 galactose + 1 glucose → 1 lactose), for the nervous system.

As previously noted, milk also contains phospholipids³⁹—as lecithin, cephalin, sphingomyelin, cerebrosides—which undoubtedly have nutritional significance.

The unique value of milk in the national health program (Sect. 20.2) consists particularly in its *supplementary* value to the prevailing refined-cereal-potato-sweets diet, especially to those in the low-income group who cannot afford to buy meat, eggs, green vegetables, and fruit (Fig. 21.2). The daily consumption of a quart of milk may render almost adequate an otherwise inadequate diet.

A century ago, the per capita consumption of pure sugar was 8 pounds a year; now it is over 100 (112 in 1941)⁴⁰. About 20 per cent of the total calories of the average consumer is furnished by sugar⁴¹, and 30 per cent of the calories is furnished by white flour. The milling process has been so perfected that modern white flour is almost completely devoid of its mineral and vitamin "impurities." (The milling process removes $\frac{1}{3}$ of the iron, $\frac{1}{2}$ of the calcium, $\frac{1}{2}$ of the copper, $\frac{1}{2}$ of the thiamine, $\frac{1}{2}$ of the riboflavin, $\frac{1}{2}$ of the vitamin B complex and nearly all the manganese and magnesium.) The net result is a marginal diet in which 50 per cent of the Calories are derived from sugar and white flour, nearly devoid of minerals and vitamins, with corresponding marginal health⁴¹. Nervous manifestations associated with beri-beri and pellagra are said to be endemic in the United States⁴², as are " . . . among other signs and symptoms, moodiness, sluggishness, indifference, fear, and fatigue." The Stiebeling reports⁴³ " . . . reveal a large pro-

portion of poor diets in peaceful America with its bursting granaries. . . . The diets were poor in vitamins A, D, and B₁ and in calcium. . . . When white flour and sugar provide 50 per cent of the calories . . . selection of a diet that can be called good . . . is almost impossible except for an expert."

The dietary complications which worry physicians⁴², food economists⁴³, and nutritionists⁴⁴ may be solved, as suggested by Sherman⁴⁵, McCollum⁴⁶, Rose⁴⁷, and others⁴⁸, by including in the diet a quart of whole milk a day. This milk corrects the faults of

Fig. 21.2. Milk, meat, and egg consumption as related to income level. Modified from "The Dairy Situation", Bureau of Agricultural Economics, U. S. Dept. Agriculture, November, 1942.

the "perversely" used impoverished foods. Moreover, milk can be made a carrier of the easily manufactured vitamins⁴⁹, as B₁, in the same manner as it is now often enriched with vitamin D.

To be sure, milk is not suitable as an *exclusive* diet after the normal weaning age.

The amounts of iron, copper, and manganese salts are inadequate in milk when fed to adult rats as an exclusive diet. (The young are born with iron and copper reserves in the liver to meet their needs during the suckling period.) But when the milk is supplemented by these salts, rats⁵⁰ and dogs^{51, 51} may be maintained almost indefinitely (for four generations at least) on the exclusive (mineralized) milk diet. They also reproduced, although at a lower rate^{50, 51}, on this diet. Calves⁵² were also grown on this mineralized milk diet for at least two years, but in addition to iron, copper, and manganese, magnesium had to be added to the milk⁵³. Milk is also inadequate in vitamin C when fed to species dependent on dietary ascorbic acid.

Fortunately, whole cereal (such as whole-wheat bread) supplements the milk deficiencies in a practically perfect manner (except for ascorbic acid). This was demonstrated by Sherman (Sect. 18.2.4), who maintained many generations of rats on an exclusive whole milk-whole wheat (and salt) diet. Sherman had two diets differing in the milk-to-wheat ratios: (1) $\frac{1}{2}$ dry whole milk and $\frac{1}{2}$ whole wheat; (2) $\frac{1}{3}$ dry milk and $\frac{2}{3}$ wheat. In comparison to a good stock diet, the rats on diet (1) performed *satisfactorily* in growth, health, reproduction, and longevity; on diets (2) they performed *excellently* in growth, health, and longevity. The most striking observation is that the rats on diet (2) matured earlier, lived longer and retained their vigor to a more advanced age. This result leads to the tentative conclusion that a whole milk-whole cereal diet (supplemented in the case of man with raw cabbage or raw or canned tomato or citrus for vitamin C) in which milk furnishes about $\frac{1}{3}$ to $\frac{1}{2}$ of the Calories (as when a daily quart of milk is consumed) is nutritionally complete. Taylor⁵⁴ suggested the combination of milk and bread into a milk-bread, which is less expensive than milk and bread. It seems agreed that most people are alike in needing milk; unfortunately, they are not alike in their ability to get it, and the basic problem is how to bring it within their means (Fig. 21.2).

21.3: Composition of milk. This section is not concerned with the details of the chemical composition of milk on which there are extensive reviews⁵⁵, but with some of its general features.

Bunge⁵⁶ suggested that the chemical composition of milk in different species is correlated with the chemical composition of the new-born animal. This correlation, if any, does not appear to be striking. More striking is the parallelism between milk composition and maturing speed of the new-born

mammal, as exemplified by Table 21.3 mostly from Abderhalden⁵⁷, who called attention to this relation. (This table is modified and extended on the basis of the newer literature⁵⁸.)

The relation between milk composition and maturing rate is complicated by many factors, evolutionary and physiologic. The milk of the ass, horse, and man is abundant in water (90 per cent) and sugar, but poor in protein and fat. The milk of the reindeer and marine mammals is very concentrated. The situation is too complex for a simple generalization, although, no doubt, speed of growth, composition and physiologic age (Ch. 19) of the young at birth are important factors in determining the evolutionary trend of milk composition. The method of obtaining the milk influences the *apparent* composition.

It is remarkable that the composition differences are no greater than they are. All milks contain the same constituents, although the proteins differ immunologically⁵⁸. Thus persons allergic to cow's milk can take goat's milk without any ill effects.

In spite of the quantitative differences in composition of the milk of different species, man and most farm and laboratory animals thrive on cow's milk. While goats (kids) make exactly the same growth per Calorie on cow's as on goat's milk⁵⁹, calves are said⁶⁰ to react unfavorably to goat's milk; and while horses (foals) are said to react unfavorably to undiluted cow's milk, they thrive on undiluted goat's milk, although goat's and cow's milk have the same quantitative composition. The differences may be associated with differences in permeability of the digestive tract lining to some of the proteins of goat's and cow's milk, with consequent allergic reactions⁶¹.

But even in the same species there is considerable difference in the quantitative composition of milk, indicated by the following cattle-breed-difference data, on small groups of animals, from Overman *et al.*⁶²

Breed Differences in Composition of Milk (small groups of animals).

Cattle, breed	Means of percentages of components							
	Fat	Protein	Lactose	Ash	Solids	Water	Solids-not-fat	Specific Gravity
Ayrshire	4.1	3.6	4.7	0.68	13.1	86.9	9.0	1.0317
Brown Swiss	4.0	3.6	5.0	0.73	13.4	86.6	9.4	1.0318
Guernsey	5.2	4.0	4.9	0.74	14.9	85.1	9.7	1.0336
Holstein	3.5	3.4	4.8	0.68	12.5	87.5	9.0	1.0324
Jersey	5.2	3.9	4.9	0.70	14.7	85.3	9.5	1.0332
Guernsey-Holstein	4.4	3.8	4.9	0.72	13.8	86.2	9.4	1.0330
Average	4.4	3.7	4.9	0.71	13.7	86.3	9.3	1.0326

⁶² Overman, O. R., Garrett, O. F., Wright, K. E., and Sanmann, F. P., *Univ. Ill. Agr. Exp. Sta. Bull.* 457, 1939.

There are, moreover, differences in composition within the breed as indicated by the following table (Overman, *et al.*).

Breed	Maximum and minimum percentages of milk constituents						
	Fat	Protein	Lactose	Ash	Solids	Water	Solids-not-fat
Ayrshire	2.9-5.7	2.9-4.6	2.4-6.1	.58-.85	10.6-15.8	89.4-84.2	7.2-10.4
Brown Swiss	2.9-6.5	2.6-5.7	3.7-6.7	.64-.99	11.4-17.3	88.6-82.7	8.0-11.4
Guernsey	3.7-7.7	2.7-5.5	3.6-5.8	.60-.85	12.1-17.9	87.9-82.1	8.2-11.1
Holstein	2.6-6.0	2.4-6.5	4.0-5.7	.56-.86	10.7-17.6	89.3-82.4	7.8-11.9
Jersey	3.3-8.4	2.9-5.8	2.7-5.7	.57-.82	11.0-11.7	89.0-88.3	7.7-11.1
Crosses	2.7-7.5	2.7-6.3	3.0-6.0	.58-.94	10.6-17.9	89.4-82.1	7.9-11.7
All samples	2.6-8.4	2.4-6.5	2.4-6.7	.56-.99	10.6-17.9	89.4-82.1	7.2-11.9

The caloric value of milk, of course, varies with its composition, especially with its fat percentage. Gaines suggested that milks of different fat percentage be converted into milk containing 4 per cent fat, designated *FCM*, which has a heat value of 750 Cal per kg, or 340 Cal per lb. According to Gaines⁶³,

$$FCM = 0.4M + 15F$$

M is weight of milk and *F* is weight of fat, all in the same units, and *FCM* is milk corrected to 4 per cent fat (see Table 22.3 for details).

The Gaines formula is based on the following combustion values per gram of milk constituent: 9.253 Cal for fat, 5.853 for protein, 3.693 for lactose; one kilogram of 4 per cent milk contains 750 Cal and 37 gm protein on the basis of 50 mg protein per Cal. The ratio of protein to energy is nearly constant, 43 to 49 mg protein per Cal, regardless of the fat percentage in milk.

The combustion energy of 4 per cent goat's milk⁶⁴ is virtually the same as of 4 per cent cow's milk: 342 Cal per lb for goat's milk, and 343 Cal for cow's milk. The combustion value of 3 samples of woman's milk was reported to be⁶⁵ 660, 680, and 770 Cal per liter.

It is often convenient to represent milk composition in terms of percentages of the total solids, or the nitrogen in terms of total nitrogen, as follows⁶⁶.

	Percentages in terms of the milk solids				Percentages in terms of total N		
	Fat	Protein	Lactose	Ash	Casein N	Albumin N	Non-protein N
Low-protein ration (N.R.1:13)	28.6	24.8	40.5	5.5	77.5	18.2	4.2
High-protein ration (N.R.1:2)	28.2	26.1	41.2	5.8	71.1	20.5	8.4

Species Differences in the Distribution of Nitrogen in Milk⁶⁸

Species	Nitrogen in milk as percentage of total N					Ratio of Albumin + Globulin N to Casein N	Gms. N in 100 cc Skim Milk
	Casein N	Globulin N	Albumin N	Total Protein N	Non-protein N		
Saanen & Toggenburg goats	71	8.2	13.2	92	8.1	0.30	0.52
Holstein cows	76	8.5	9.6	94	6.2	0.24	0.50
Jersey cows	81	5.5	9.3	96	4.5	0.19	0.64
Human (one sample)	41	15.0	27	84	16	1.0	0.18

⁶³ Gaines, W. L., Ill. Agr. Exp. Sta. Bull. 308, 1928. Overman, O. R., and Gaines, W. L., *J. Agr. Res.*, **46**, 1109 (1933).

⁶⁴ Peterson, V. E., and Turner, C. W., *J. Nut.*, **17**, 293 (1939).

⁶⁵ Shukers, C. F., *et al.*, *J. Nut.*, **5**, 127 (1932).

⁶⁶ Perkins, A. E., Ohio Agr. Exp. Sta. Bull. 515, 1932.

Incidentally, Perkins' table⁶⁶ shows that the dietary protein level may influence the percentage distribution of protein and especially non-protein nitrogen in the milk.

The table of Gamble, Ellis, and Gross⁶⁹ shows that in terms of percentage of total nitrogen, goats and cows have nearly the same composition, but human milk contains about half the casein, and double the albumin, globulin, and non-protein nitrogen as cow's or goat's milk. This may be associated with the younger physiologic age of human infants than those of cows or goats, since the non-casein nitrogen of milk is more closely related to blood nitrogen than is the casein nitrogen; and judging by the composition of colostrum, the younger the physiologic age of the newborn, the richer the milk in noncasein nitrogen.

The data of Gamble, Ellis, and Besley apparently show closer agreement in quantitative composition between goat's and Holstein-cow's milk than between Holstein and Jersey cow's milk, in spite of differences in mature weight, rate of physiologic maturation and growth, and different evolutionary history. This is also shown in the following summary of the species differences in the composition of milk.

	Fat (%)	Protein (%)	Lactose (%)	Ash (%)	Water (%)	Ca (mg %)	P (mg %)	Fe (mg %)	Cu (mg %)
Goat	3.5	3.1	4.6	0.79	88.3	114	98	0.072	0.053
Holstein cow	3.4	3.2	4.6	0.70	88.2	106	88	0.072	0.057
Jersey cow	5.3	3.8	4.7	0.73	85.7	117	101	0.088	0.058
Human ⁶⁷	3.5	1.3	7.5	0.2	88	34	15	0.2	0.05
Rat ⁶⁸	15	12	2.8	1.5	69	349	270	0.7	0.7
Dog ⁶⁹	8.3	7.5	3.7	1.2	77	289	240		

The rate of growth of suckling rats and human infants was almost identical per Calorie intake of goat's and Holstein's milk.

It is interesting to note that in spite of the enormous differences in the percentages of calcium and phosphorus in the milk of cow, rat, and dog, the Ca:P ratio is 1.2, the same in all. In human milk, the ratio is 2.3. These unusually high Ca:P ratios, rarely found in other foods, are very favorable for calcium assimilation. Milk is thus the best nutritional source of calcium, not only because of its richness in calcium, but also because of the favorable Ca:P ratio.

Summarizing, the qualitative composition of different milks is chemically (not always immunologically) the same, but different in the proportions between the constituents. While the composition tends to vary with the rate of maturing of the newborn animal, other factors confuse this relation.

21.4: Physico-chemical aspects of lactation. (See Sect. 7.2 for hormonal aspects.) The concentration of some substances, such as urea⁷⁰, is the same in milk and blood; the concentration of most constituents in milk differs from that in blood. Thus⁷¹, in comparison to blood, cow's milk contains 40 times as much sugar⁷² on a molar basis, and 80 to 90 times on a gravimetric basis⁷³; 20 times as much fat, 14 times as much calcium, 7 times as much

⁷² Petersen, W. E., *J. Dairy Sci.*, **25**, 71 (1942).

⁷³ Comparison of the blood and milk sugars of several species.

	Cow	Goat	Sheep	Rabbit	Mare	Sow	Dog	Rat	Woman
Blood sugar (%)	0.05	0.06	0.06	0.12	0.11	0.13	0.08	0.12	0.11
Milk sugar (%)	4.6	4.6	4.5	2.0	7.0	4.0	3.7	3.0	7.0

potassium and phosphate, 4 times as much magnesium, $\frac{1}{2}$ as much protein, $\frac{1}{2}$ as much chlorides, and $\frac{1}{2}$ as much sodium. Some typical milk constituents, such as casein, lactose, and the short-chain fatty acids, are absent in blood.

21.4.1: Osmotic pressure and milk synthesis. In spite of the greater gravimetric concentration of most constituents in milk, the osmotic pressure is the same, about 6.6 atmospheres, in milk and blood, indicating the same total osmotically active molar concentration. How is this sameness of osmotic pressure in milk and blood maintained in the face of the differences in gravimetric composition? Perhaps by the enzymatic change of osmotically active, smaller-molecule transudates derived from blood into osmotically less active, larger-molecule milk constituents. Thus one molecule of milk sugar is derived from two molecules of blood sugar, or from one glucose and two lactic acid molecules, thereby reducing the osmotic pressure in the blood transudate by $\frac{1}{2}$ or $\frac{2}{3}$. Similarly, the amino acids, phosphates, calcium ions, etc., are combined in the secretory cells into larger aggregates—into casein, lactalbumin, and calcium caseinate—resulting in an overall lower osmotic pressure. The osmotic pressure reduction in the transudate in the secretory cells below that of the blood drives the diffusible substances from the blood into the secretory cells as part of the tendency to equalize the hydrostatic or diffusion pressure.

Disturbance of the mammary apparatus, exemplified by mastitis, due to engorgement of the secreting alveoli with fluid as result of cessation of customary milking, affects the selective action of the gland, with a resulting tendency to equalization of milk and blood-serum constituents; this is indicated, for example, by increase in the pH, chloride, catalase, and globulin of milk and decrease in its casein and lactose. Indeed, milk from disturbed glands is detected by its high pH, chloride, and catalase.

The rate of secretion and (to a lesser extent) the composition of milk depend on the pressure within the secretory alveoli. The higher the intra-alveolar pressure, the less the rate of milk secretion and the greater the tendency of the composition of milk to approach that of blood serum. This statement may be illustrated by several dramatically important applications:

(1) When the blood calcium (and sometimes blood sugar) declines below a critical level as result of too rapid lactation (in comparison to the animal's ability to mobilize calcium), the animal develops the typical hypocalcemic and/or hypoglycemic syndrome *milk fever*. Death follows if this is untreated. But if the udder is pumped full of air, both lactation and the drain of blood calcium into the milk are stopped; indeed, some of the calcium in the milk may be turned back to the blood, with the result that the blood calcium (and/or sugar) attains a normal level. Thus, instead of dying, the cow may become normal in a few minutes—an apparent miracle has been performed.

(2) Lactation may be stopped at any time by merely ceasing to milk. The increase in intra-alveolar pressure as a result of failure to remove the milk effectively blocks the lactation process. The applications of this fact are evident: the more frequent and the more complete the milkings, the lower

the average intra-alveolar pressure and the greater the rate of milk secretion; or what is the same, the longer the interval between milkings, the less the milk production per unit time. This is illustrated by the declining curve in Fig. 21.3, prepared from data secured in 1920 or 1921⁷⁴.

Fig. 21.3. The influence of milking frequency on the rate of milk production.

(3) Unsatisfactory performance, especially rapid "drying up," in some otherwise good dairy cows is explained⁷⁵ by the failure of the cow to "let

⁷⁴ Univ. Mo. Agr. Exp. Sta. Res. Bull. 96, 1926, pp. 82. For the more recent literature see Petersen.⁷³

⁷⁵ Petersen,⁷³ Turner, C. W., *Hoards Dairyman*, 88, 685 (1943). Hammond, J., *J. Vet. Rec.*, 16, 519 (1936).

down" her milk, with resulting continuous high pressure in the alveoli. The "let-down" mechanism is apparently neuro-endocrine in nature. The stimulation (by milking) of the nerve endings in the teat and udder is carried to the central nervous system, which in turn stimulates the posterior pituitary to eject the oxytocic hormone into the blood; the oxytocic hormone stimulates the muscles around the alveoli to contract and thus eject the milk. On the other hand, when the cow is excited, adrenaline production (by the adrenal medulla) is accelerated, thus relaxing the smooth muscles, that is, preventing the muscles around the alveoli from contracting for milk ejection^{75, 76}.

The involvement of the nervous system is demonstrated by the eventual loss of ability to "let down" the milk following sympathectomy⁷⁷ and by similar failure when the animal is frightened or annoyed⁷⁶. Good dairymen, of course, know that it is important to handle cows gently, quietly, and pleasantly (see Sect. 10.8 for a discussion on a broader plane).

The speed of synthesis and diffusion of the various milk constituents is dependent, among other factors, on (1) concentration of milk precursors in the blood, which depends on food supply; (2) concentration of synthetic enzymes in the secretory cells, dependent on the genetic constitution of the animal (although the immediate control of the enzyme concentration may reside in the pituitary or other endocrines, which are directly or indirectly related to the genetic constitution of the animal); (3) intra-alveolar pressure and the factors controlling it.

The concentrations of water, solids, and each of the solid constituents in milk depends on the relative concentrations of each of the various enzymes in the secretory cells. Thus if the concentration of the lactose-synthesizing enzymes is high, relatively more lactose will be produced. Since per unit weight lactose is osmotically more active than fat or protein, the milk will contain more water in order to maintain the osmotic pressure constant. This is probably the reason why the higher lactose concentration in the milk of the horse, ass, and man is associated with higher water content (more dilute⁷⁸).

21.4.2: Colostrum. Colostrum, the mammary secretion in the early stages of lactation, is in some respects intermediate between blood serum and normal milk, especially in being rich in globulin and albumin, poor in potassium and high in sodium, poor in lactose and high in chlorine, as illustrated by Table 21.4, computed by us from Garrett and Overman⁷⁹. The following data on the composition of colostrum during the first four days after calving (Fig. 21.4a) may also be of interest⁸⁰.

Fig. 21.4a.
Change in composition from colostrum to milk.

In addition to the unusually high level of protein (especially globulin), colostrum is also very rich in vitamin A, perhaps 100-fold that in normal milk, and in other substances, such as immune bodies required by the young until it develops its own immunity⁸⁰, and in lysozyme⁸¹. There are also considerable post-colostral changes in the composition of milk, as indicated in Fig. 21.4.

21.4.3: Synthetic powers of the mammary gland. Since, as above explained, milk contains casein, lactose, and short-chain fatty acids not found in blood, and since the general level and proportions of the several constituents in milk are different from those in blood serum, it follows that the mammary gland has synthetic and selective powers. Mammary tissue slices also exhibit synthetic powers *in vitro*. This was demonstrated especially for the synthe-

sis of lactose from glucose⁸² *in vitro*. It has long been known⁸³ that there is an arterio-venous difference in the constituents going to make up milk, indicating that the mammary gland takes up the constituents from the blood to make milk. However, the intermediate metabolism, the stages through which the blood constituents pass on their way to milk, is still a virgin field of investigation.

Fig. 21.4d. Change in composition of fat with the advance of the period of lactation. The first numeral on each line represents the corresponding absolute number, e. g., 4.0% fat.

Even the technique of drawing blood for evaluating the uptake of blood constituents for milk production has not yet been worked out satisfactorily. Kaufmann and Magne⁸⁴ assumed that the difference in composition between jugular blood and mammary-vein blood represents the uptake by the mammary gland. Blackwood & Stirling⁸⁴ criticized this method especially because it overlooks the differences in blood composition resulting from differences in the rate of salivary secretion. Blackwood and Stirling⁸⁴ ob-

tion of the blood, especially the blood-sugar level. Anesthetizing the animal⁹⁰ may overcome this difficulty but introduces others.

To be useful for quantitative interpretation, measurements of arterio-venous difference in blood composition must be accompanied by measurements of the rate of blood flow through the mammary gland. Graham⁹¹ employed the thermostromuhr method⁹² for this purpose.

The earlier data of Graham⁹³ *et al.* and also of Shaw and Petersen⁹⁴ (computed on the basis of calcium intake) indicate that about 400 volumes of blood pass through the udder in producing one volume of milk. This means that 20,000 pounds of blood pass through the udder in producing 50 pounds of milk. Graham's thermostromuhr method, however, gave much lower values⁹⁵.

21.4.4: Milk-sugar production. Graham reported that milk sugar is derived not only from glucose but also from lactic acid⁹⁶ and from blood protein⁹⁷. Some lactose may also be produced from glycoproteins⁹⁸.

These results are important because they demonstrate that: (1) blood sugar is not the only source of milk sugar; (2) lactic acid, an important rumen-fermentation product, may participate in and accelerate lactose formation—and, therefore, milk secretion—in ruminants; (3) high dietary protein may stimulate milk secretion; (4) the mammary gland resembles the heart, liver, and other organs in normally utilizing lactic acid for functional activity. It is believed that blood-sugar level is at least one of the major limiting factors in milk secretion; the production of lactose by the mammary gland is believed to control milk volume: 18 lbs of water goes with 1 lb of lactose. Anything which reduces blood sugar (as phlorizin) reduces mostly the milk secretion rate⁹⁹ rather than concentration of sugar in milk, although there may also be a reduction in the lactose level of the milk^{99, 100}. Alimentary hyperglycemia is, however, without effect; the excess sugar is simply excreted.

21.4.5: Milk-protein production. It is known that there is less nitrogen in mammary-venous than in arterial blood¹⁰¹. It is not known, however,

⁹⁴ Shaw, J. C., and Petersen, W. E., *Am. J. Physiol.*, **123**, 183 (1938).

⁹⁵ Computation example: if the arteriovenous difference for calcium is 0.31 mg % and the milk calcium is 120 mg %, the ratio of volume blood flow through the mammary gland to the amount of milk secreted is $120/0.31 = 387$. For fat: if the arteriovenous difference, 11.6 mg. % is divided by milk fat content, 400 mg %, it yields a ratio of 344. For lactose: the ratio of milk sugar to blood sugar + lactic acid = $4860/12.4 = 391$ volumes of blood to 1 of milk produced. Graham's stromuhr method yielded the ratio 140 to 223 in milking goats and 400 in an almost dry goat.

to what extent each of the various nitrogen compounds in blood is transformed into the various nitrogen compounds in milk. The difference in amino acids in the arterial and venous bloods is not sufficiently great to account for the milk proteins¹⁰², especially as amino acids are also used in production of lactose. Incidentally, the production of lactose from amino acids, of course, involves deamination and urea production, so that the mammary venous blood contains 3 per cent more urea (1 mg per cent more) than arterial blood. Indeed, the increase in urea nitrogen in the mammary vein may be equivalent to the amino-nitrogen taken up by the gland to produce milk protein¹⁰³. These masking effects and other complications make it difficult to interpret the significance of simple arterio-venous nitrogen differences. It is now believed^{89, 90, 91} that blood globulin, including glycoprotein, is taken up by the mammary gland. There are many data which bear on but do not clarify the problem of milk-protein synthesis, such as that there is much more globulin in lactating than in non-lactating gland tissue¹⁰⁴, and that mammary-gland tissue contains considerable arginase¹⁰⁵ (enzyme for splitting urea from arginine).

Summing up, Graham *et al.*¹⁰⁶ seem to have demonstrated that only about 40 per cent of the milk protein is derived from blood-serum amino acids, the remainder comes from blood-serum globulins and unidentified nitrogen compounds. This result was confirmed by Shaw and Petersen¹⁰⁷, and others¹⁰⁸.

21.4.6: Milk-fat production. Meigs¹⁰⁹ *et al.* reported a jugular-mammary vein difference in lipid phosphorus, and so concluded that milk fat is derived from blood phospholipids. Subsequent investigators¹¹⁰ however, found no arterio-venous differences in phospholipids, but differences in total fatty acids, and so concluded that milk fat is derived from neutral fat, perhaps almost exclusively from blood fat.

The respiratory quotient is ordinarily a good index of the nature of the metabolites involved in a given transformation (Ch. 12). Thus an R.Q. of 1.0 indicates that carbohydrate is oxidized; and R.Q. above 1.0 indicates that fat is synthesized. R.Q. measurements of the mammary gland at Missouri¹¹¹ yielded values considerably above 1.0 (average of 1.36), indicating synthesis of a portion of the milk fat from blood carbohydrate. The R.Q. values

ranged¹¹² from above unity in the lactating mammary gland of goats, to 0.8 in non-lactating, indicating synthesis of milk fat, especially short-chain fatty acid fats, from blood carbohydrate. It is, however, more generally believed¹¹³ that the short-chain fatty acids in milk are derived from long-chain fatty acids, perhaps from breakdown of oleic-acid fats, in blood¹¹⁴.

There is a considerable literature on the qualitative influence of the dietary fat on milk fat¹¹⁶. Broadly speaking, such characteristics as the iodine number or hardness of the butterfat tend to parallel within certain limits the corresponding characteristics in the dietary fat. One observer reported that 18 per cent of dietary oil was recovered unchanged in the milk¹¹⁷. However, most milk fat is synthesized by the mammary gland, since the chemical composition of milk fat as a whole differs from body and food fat. One of the important contemporary problems in lactation research is the elucidation of the paths, time rates, and mechanisms of these and related transformations. The method of tagging dietary constituents with isotopes, such as with deuterium¹¹⁸, radioactive iodine¹¹⁹ and sulfur, heavy carbon¹²⁰ and nitrogen should prove helpful in tracing dietary carbon, hydrogen, sulfur, and nitrogen to milk carbon, hydrogen, sulfur and nitrogen¹²¹. The use of isotopically labelled compounds is undoubtedly the next stage in the study of the intermediate metabolism of milk secretion. Unfortunately, this method is not suitable for experiments with ruminants.

21.4.7: Influence of dietary fat level and of fasting on milk and butterfat production. About a century ago Lawes and Gilbert¹²² demonstrated massive conversion of dietary carbohydrate into body fat in farm animals, and about a half century ago Jordan and Jenter¹²³ similarly demonstrated massive

¹¹² Reineke, E. P., Stonecipher, W. C., and Turner, C. W., *Am. J. Physiol.* **132**, 535 (1941).

¹¹³ Reineke, *et al.* feel that if the milk fat all comes from blood fat, there should be no decline in short-chain fatty acids during fast when less blood sugar is available for fat formation. Fasting reduces the R.Q. of the lactating mammary gland to 0.8 and also reduces short-chain fatty acids, which accords with the expectation if the short-chain fatty acids are derived from blood lactic acid or glucose.

conversion of dietary carbohydrate into milk fat in cattle. However, a certain amount of dietary fat is desirable for optimal production of body fat or milk fat. Thus Maynard¹²⁴ and associates demonstrated that dairy animals fed a hay-silage-grain ration containing 6 per cent fat produce above those fed a ration containing 0.7 per cent fat; and cows fed a ration containing 5 per cent fat produce above those fed a ration containing 3 per cent fat¹²⁵: "For feeding practice, it is tentatively concluded that a level of 4 per cent fat in a grain mixture, which is fed at the rate of 1 lb for every 3 to 3½ lbs of milk along with an adequate amount of hay and corn silage, may be considered as substantially adequate." More recently Maynard¹²⁶ and associates reported that cows fed a ration containing 7 per cent fat produce 4.4 per cent more milk, 2.0 per cent more fat, and 4.1 per cent more FCM (milk reduced to a 4 per cent fat basis) than cows fed a ration containing 3 per cent fat. Feeding grain mixtures ranging from 2.7 to 4.9 per cent fat did not affect the milk or fat yield in milk cows¹²⁷. Most of the literature¹²⁸ is not so clear-cut because of complicating experimental factors which are difficult to interpret. For example, the milk yield may be limited by the animal's capacity to handle bulk, and since a fat-rich ration has less bulk per calorie, the animal may be able to consume more available calories in the diet in the high-fat ration than in the more bulky fat-poor ration and, therefore, yield more milk on the high-fat ration. This is evidently not a fat effect but a bulk effect. Replacing the bulky roughage by iso-caloric quantities of fat-poor grain might have a similarly stimulating effect on milk production.

The feeding of cod-liver oil lowers the milk fat¹²⁹ (the depressing factor was traced to the triglyceride factor, not the non-saponifiable factor¹³⁰) without, however, affecting the blood lipoids.¹³¹

Broadly speaking, while reducing a dietary or blood constituent below a certain level lowers the milk yield and often lowers the concentration of this constituent in the milk, the opposite effect, namely, raising the dietary or blood constituent above a certain level, is usually without effect on milk yield or milk composition.

For instance, decreasing blood sugar by insulin or phlorizin decreases milk yield; but increasing blood sugar above the normal level does not influence¹³²

the lactose per cent in milk or the milk yield. Likewise, decreasing the protein¹³³ content below about 16 per cent in the ration of milking cows may depress milk yield; but increasing it above this level does not increase milk yield or change the composition. However, some diffusible constituents in milk not synthesized by the mammary gland, such as vitamins A and D, may be increased enormously above the normal level by their dietary or blood increase.

Related to the problem of dietary level is that of fasting on milk production and composition. As expected, continued fasting lowers the milk yield; but unexpectedly, it raises the concentration of most milk constituents (fat, protein, ash, total solids), though it lowers some, especially lactose. Figs. 21.10 and 21.11 indicate how the percentages of the various milk constituents change with advancing fast. The nature of the changes varies with the time of fast, stage of lactation, individuality of the animal, nutritive condition and so on.

These time changes for 6 days (144 hours) in milk yield and composition do not precisely reflect (except possibly in the sugar) the quantitative time changes in the composition of blood, as illustrated by the following data¹³⁴ on blood. The important effect of fasting on lactation may be by way of the influence on the lactogenic hormones, which influence has not yet been investigated.

The following comparisons, modified from Smith¹³⁵, on a lactating Ayrshire cow indicate a similar lack of correlation between milk and blood composition.

	Blood serum phosphatase units (%)	Milk phosphatase units (%)	Blood Serum Cl (mg %)	Milk Cl (mg %)	N partition in milk as % of total N				Blood Serum Ca (mg %)	Corpuscular volume (%)
					Casein	albumin + globulin	Non-protein	Protein		
Before fast	4.7	35	350	100	78	15.0	6.5	93	10.5	32
5th day fast	3.0	145	347	107	75	17	7.0	93	9.8	40
10th day fast	4.1	141	337	128	74	19	7.0	93	10.2	41

As previously noted, the nature of the diet changes to some extent the composition of the milk fat. The advance of the period of starvation changes the nature of the nutrients available for the mammary gland, and consequently changes to some extent the nature of the milk fat. Thus the iodine values rise (from 37 to 53) and the Reichert-Meissl value declines (from 25 to 9) during fast¹³⁶.

Summarizing this section as a whole, milk is produced in the secretory cells of the mammary gland in several steps, first by filtration, then by synthesis of the major transudate constituents into larger molecules, such as lactose, from glucose and from lactic acid. Such synthesis of one large molecule from several smaller ones produces an osmotic-pressure gradient, forcing more blood transudate into the secretory cells. The rate of milk production is dependent on several factors: (1) the rate of synthesis in the secretory cells,

¹³³ See, among others, Harrison, E. S., and Savage, E. S., Different planes of protein intake and milk production. N. Y. (Cornell) Agr. Exp. Sta. Bull. 540, 1932, and Bull. 578, 1933.

¹³⁴ Aylward, F. X., and Blackwood, J. H., *Bioc. J.*, **30**, 1819 (1936).

¹³⁵ Smith, J. A. B., Howat, G. R., and Ray, S. C., *J. Dairy Res.*, **9**, 310 (1938).

¹³⁶ Smith, J. A. B., and Dastur, N. N., *Bioc. J.*, **32**, 1868 (1938).

(2) the concentration of milk precursors in the blood, and (3) the rate of blood circulation through the mammary gland. Measurements of mammary arterio-venous differences in blood composition indicate that: (1) milk sugar is normally produced from (a) blood sugar, (b) lactic acid, (c) protein; (2) milk protein is produced from (a) blood amino acid (up to about 40 per cent), (b) blood-serum globulin and unidentified substances; (3) milk fat from (a) blood-serum fat (or equivalent), (b) blood sugar and possibly blood lactic acid and protein.

Reducing blood sugar or other constituents below their normal levels depresses milk production and reduces the percentage of its constituents; but increasing blood sugar or other blood constituents above their normal levels does not usually increase milk production, or the percentage of sugar, fat, or protein in the milk. For instance, adding fat to a cattle ration already containing 4 per cent fat does not appreciably increase the fat percentage in the milk.

Some diffusible substances not synthesized by the mammary gland, such as iodides and some of the vitamins, tend to enter the milk in some proportion to their concentration in the blood. In this way cow's milk may be enriched in these substances by dietary methods, *e.g.*, with vitamins A (from 400 units per quart on winter feed to 2200 on green summer pasture), with vitamin D (from 5 units per quart in winter light to 50 units in summer sunshine and 160 on feeding about 200 gm or $\frac{1}{2}$ lb irradiated yeast per day), or with iodide (Ch. 6); it cannot, however, be enriched appreciably with calcium, iron, copper, or thiamine, (human milk apparently can be enriched with thiamine by dietary means¹³⁷).

The operation of the law of diminishing returns (Ch. 1) relating the concentration of milk and feed constituents may be illustrated by the following values on the relation between vitamin D in milk and feed.

Vitamin D units fed to cows	0	600	1400	40000	60000
Vitamin D units per quart milk	3	5	10	20	30

There are large bodies of data on such relations by the Ohio and Wisconsin workers and others.

21.5: The heat increment of lactation during feeding and fasting. As might reasonably be expected, the lactation process involves an extra energy expense or heat increment above the non-lactating level. The milk precursors are assembled and synthesized into milk; the lactating mammary gland has more physiologically active tissue; the endocrine system (especially thyroid and pituitary) is physiologically more active during lactation; two to three times more food is ingested during lactation (Fig. 14.20c). Each of these processes involves some form of "work" (Chs. 2 to 5), which, of course, takes place at an energy cost. We shall indeed demonstrate that the heat

¹³⁷ Donelson, E. G., and Macy, I. G., *J. Nut.*, 7, 231 (1934).

production during heavy lactation is about 100 per cent above that during the non-lactation level in spite of the following conclusion to the opposite: "...lactation does not increase the heat production. This is not strange, since the arrangement of food materials in the preparation of milk depends upon the hydrolytic cleavages and syntheses which involve hardly any thermal action¹³⁸." This conclusion¹³⁸, generally quoted in textbooks, is based on heat production under basal conditions, that is heat production during fast,

Fig. 21.5a. The influence of lactation on heat production. The smooth lines represent heat production of non-lactating animals (the lower line for mature animals of different species, the upper line for rats of different size assuming, the same 0.73 slope of the line).

and we shall show that fasting depresses lactation and heat production. Under ordinary conditions, of course, lactating animals do not fast; indeed, they consume two or three times as much food as non-lactating animals (Fig. 14.20c). As aforementioned, their heat production is perhaps twice as

¹³⁸ Lusk, G., "The Science of Nutrition," Philadelphia, 1928.

great as that of non-lactating animals, the exact value depending on the lactation level, and therefore food intake. Let us clarify this statement by analyses of data.

21.5.1: The heat increment of lactation during normal feeding. Figs. 21.5a to c show¹³⁹ that the heat production in lactating rats may be 100 per cent above the non-lactating level. Fig. 21.6 compares similar curves for dairy cattle and rats (assuming that heat production/(weight)^{0.75} is a comparable ratio in cattle and rats). Figs. 21.7a and b show heat produc-

Fig. 21.5b. Time curves of metabolism with the advance of the period of gestation, lactation, and post-lactation rest.

tion as a function of milk production in rats¹⁴⁰ (taking the litter size in rats as index of milk production) and goats. Whichever representation method is

¹³⁹ Brody, S., Riggs, J., Kaufman, K., and Herring, V., "Energy metabolism levels during gestation, lactation, and post-lactation rest," Univ. Mo. Agr. Exp. Sta. Res. Bull. 281, 1938.

¹⁴⁰ Washburn, L. E., Brody, S., and Ragsdale, A. C., "Influence of fasting and re-feeding on milk production," *Id.*, Res. Bull. 295, 1939.

employed, the result is the same: heat production in non-fasting animals is proportional to milk production.

The high heat increment of lactation is not due to higher physical activity during lactation because, as shown in Fig. 14.20c, physical activity during lactation is considerably below the non-lactating level. Fig. 14.20c also shows that food consumption during the lactation peak is approximately three times that of the prelactation level. The high lactation heat increment is thus shown to be associated with the high food consumption and milk production rather than with physical activity.

Fig. 21.5c. The relative influence of gestation, lactation, and post-lactation rest on body weight, and heat production per day and per (weight).⁷³ on four successive litters of rat 9419. Note the influence of the number of young on the metabolism level.

21.5.2: The heat increment of lactation during fast. Depending on the rate of milk flow, lactation may treble the food consumption of the non-lactating state (rats¹⁴¹, women¹⁴², cattle), and it is not surprising that the heat production is also increased. Lusk's conclusion that "lactation does not increase heat production" refers, on the contrary, to a post-absorptive or fasting condition, which tends to depress, perhaps stop, the milk flow. We propose to substantiate the statement that even a relatively short fast virtually stops lactation in the sense of milk yield.

¹⁴² Macy, I. G., *et al.*, *J. Nut.*, **4**, 399 (1931).

Fig. 21.6. Heat production per weight^{0.75} as function of time during gestation and lactation in cattle and rats, assuming that the ratio $\frac{\text{heat production}}{(\text{weight})^{0.75}}$ is comparable for the two species.

Let us first discuss the influence of fasting on the milk production and heat production in rats¹³⁹. The change in body weight of the 10-day old litter during a 45-minute suckling is taken as index of the litter "food intake", or of the mother rat's milk production.

Fig. 21.8, lower curve, shows that within 10 hours after the food was removed from the cage, the litter "food intake" became zero; that is, the mother's milk production declined to an insignificant level. In the same time, the mother's R.Q. declined from 1.0 or over, to nearly 0.7, indicating that the available carbohydrate in the lactating mother rat disappeared within 10

Fig. 21.7a. Heat production as function of litter size and litter-weight gain which, of course, tends to be proportional to milk production of mother rat and related data. The space between the broken lines represents $\frac{1}{2}$ of the data points.

hours after the food was removed; and the mother's metabolism declined from about 50 to 35 Calories. The baby rats died of starvation within 4 days of the mother rat's fast. Incidentally, this chart shows that milk is not produced at the expense of the mother's stable tissues because the mother fasted 7 days, and recovered on refeeding, while her young died in less than 4 days.* If lactation occurred at the expense of the mother's stable tissues, lactation would continue to the end and mother and young would die at approximately the same time. It can thus be concluded that it is true that the

basal metabolism of "lactating" rats is no greater than that of non-lactating, because under conditions of basal metabolism there is practically no lactation, and consequently no heat increment of lactation.

Fig. 21.9 shows that the parallelism holds not only for fasting but also for refeeding. Normal milk production almost perfectly parallels feed consumption, heat production, and R.Q.

Fig. 21.7b. Heat production per 12-hour period above the basal level plotted against milk production during fast and refeeding of goats. The data points representing successive 12-hour periods are numbered serially. $S_{y,x}$, the standard error of Y about the equation line (Y as a function of x), has a value of 61, which means that the heat production above basal can be estimated from the equation with the odds 68 out of 100 that the error will not exceed 61 Calories.

Similar results were obtained on goats¹⁴³ (Fig. 21.10) and cattle¹⁴³ (Fig. 21.11).

Although we have no data on the influence of fasting and refeeding on milk secretion and heat production in women, data on rats, goats, and cattle demonstrate that milk production, heat production, and respiratory quotient fall

¹⁴³ Washburn, Brody, and Ragsdale¹⁴⁰. The curves for the goats were plotted from original data; the curves for the cattle were plotted from data by Overman, O. R., and Wright, K. E., *J. Agr. Res.*, **35**, 637 (1927).

and rise in percentage parallel with fasting and refeeding. Hence the conclusion that there is a large heat increment and energy cost of lactation. Lactation is said to begin in the later half of gestation; lactation is an outgrowth of gestation (Sect. 7.2). The problem of prenatal growth and metabolism during gestation was previously discussed (Sect. 14.7, see Figs. 14.17 to 14.23).

21.6: Energetic efficiency of milk production. The overall economy of milk production is composed of many elements, the two outstanding of which are (1) energetic efficiency of the lactation process discussed in this section;

Fig. 21.8. The course of: heat production (Cal/day and Cal/kg/day), R.Q. (respiratory quotient) and litter "food intake", with time after feeding of the mother. Note the parallelism between the R.Q. of the mother and the "food intake" of the litter. Note that the gain in weight of the litter during 45-minute suckling declined from three gm. to zero within eight hours after the food was removed.

(2) size of animal, "dairy merit", and plane of nutrition discussed in the following chapter.

As defined elsewhere (Chs. 1 and 22), *gross* energetic efficiency of milk production is the ratio of milk calories produced to feed calories consumed, *including maintenance cost*; *net* energetic efficiency is the ratio of milk calories to feed calories *above the maintenance cost*.

$$\text{Gross efficiency of milk production} = \frac{\text{milk calories produced}}{\text{feed (TDN) calories consumed including maintenance cost}} \quad (21.1)$$

$$\text{Net efficiency of milk production} = \frac{\text{milk calories produced}}{\text{feed (TDN) calories consumed above the maintenance cost}} \quad (21.2)$$

Fig. 21.9. The influence of fasting and refeeding of mother rat on her milk production (measured by litter-weight gain during suckling), metabolism, body weight, and R.Q. Note the prompt decline in "litter food intake" and metabolism on fasting and rise on refeeding.

If body weight is unchanged during lactation, the *gross* efficiency is computed by replacing the numerator in equation (21.1) by the milk energy, according to the method of Gaines¹⁴⁴ (convert milk to FCM from Table 22.2 and multiply FCM pounds by 340, the caloric equivalent per pound FCM); and by replacing the denominator by the TDN energy consumed (multiply pounds TDN by 1814, the assumed caloric equivalent per pound TDN). Equation (21.1) then becomes:

¹⁴⁴ Gaines, see Table 22.3.

$$\text{Gross efficiency of milk production} = \frac{340 \times \text{FCM (lbs)}}{1814 \times \text{TDN (lbs)}} \quad (21.3)$$

In addition to the overall gross and net efficiency categories as defined above, one may measure the efficiencies of the various component processes as, for example, the energetic efficiency of the mammary gland alone in assembling the milk precursors in the blood and synthesizing them into milk.

Graham¹⁰² and associates at the Missouri Station indeed computed the mammary-gland energetic efficiency from the arterio-venous differences in

Fig. 21.10. The lower half represents comparison of the time curves of milk production (curve 9), heat production above base (curve 8), and R.Q. above 0.7 (curve 9), all in terms of percentage of normal initial values. Note the striking parallelism of these curves for goats and compare to the parallelism of the curves in Fig. 8 for rats. The upper curve represents the time changes in composition of the milk with advancing fast and refeeding.

oxygen and carbon dioxide content. They reported that the gross efficiency of the mammary gland, including its maintenance cost, is approximately 90 per cent; that is, 10 per cent of the milk-precursor energy entering the mammary gland was expended for the synthesis of milk from its precursors, and for the maintenance of the gland¹⁴⁵. Thus, for example, if an 1100-lb cow

¹⁴⁵ The efficiency was computed from the ratio:

$$\frac{\text{Blood flow} \times 100}{\text{milk yield}} \times 1.09 (\text{CO}_2 \text{ vol. \%} - \text{O}_2 \text{ vol. \%}) + 5.01 (\text{O}_2 \text{ vol. \%}) + \text{milk energy/cc milk}$$

The ratio of blood flow through the mammary gland to milk produced ranged from 150:1 to 250:1; arterial O₂, 12.87 mg.%; mammary vein O₂, 7.53%; O₂ decrement, 5.34 mg.%; arterial CO₂ increment, 6.86%; R.Q., 1.3; milk energy, 80.65 Cal per 100 cc.

produces 40 lbs FCM or 13600 Cal of milk, 10 per cent of this value, that is 1360 Cal of energy is wasted, *i.e.*, given off as a heat increment of mammary-gland activity. Incidentally, since the "basal metabolism" of a 1100-lb cow is about 7000 Cal, the 1360 Cal heat increment of mammary-gland activity constitutes nearly 20 per cent of the basal metabolism. It was noted in the previous section that the heat increment of heavily lactating animals is about 100 per cent above that of the non-lactating level.

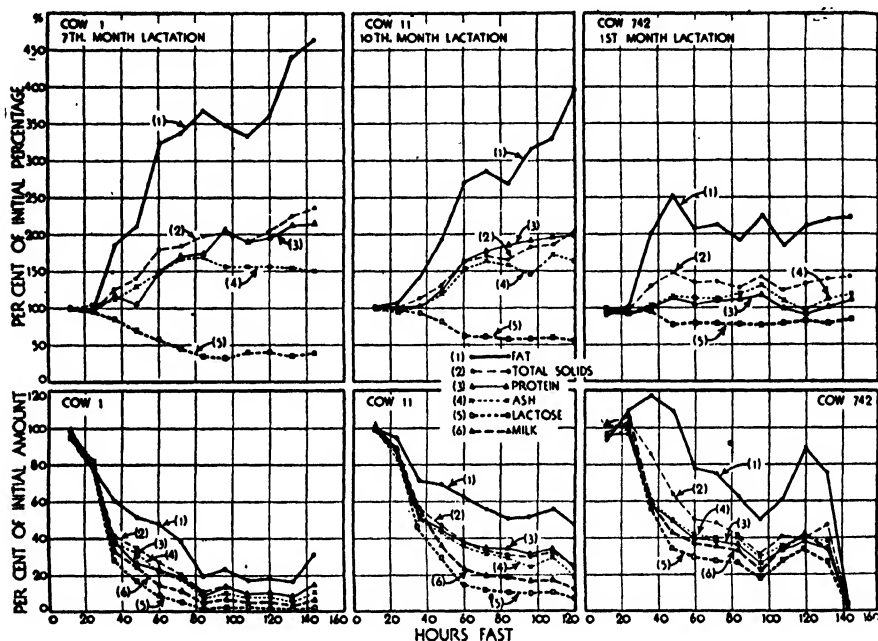

Fig. 21.11. Fasting dairy cows for 3 days (said to be the time required to attain the post-absorptive level for "basal metabolism" in cattle) reduces milk yield to 5-20 per cent of the original level (depending on the stage of lactation and individuality of the cow). This result substantiates the conclusion based on the rat and goat data that it is not possible to measure the basal metabolism of animals yielding *normal* amounts of milk because the fast required for *basal* metabolism profoundly depresses milk production. The upper curves represent changes in percentage composition of milk; the lower curves, changes in absolute yield; both upper and lower curves are represented in terms of percentages of the initial values. From the upper curves, note that fasting, which reduces milk yield increases fat percentage (1) but reduces lactose percentage (5).

21.6.1: Gross efficiency of milk production in dairy cattle. Using equation (21.3) above, we¹⁴⁶ computed, first, the gross efficiency of milk production of 368 dairy cows (data in Table 21.7) with the results summarized in Table 21.6. These tables show that the given cows—weighing from 1000 to 1300 pounds, producing 28 to 50 lbs FCM and consuming 17 to 28 lbs TDN per day—pro-

¹⁴⁶ Brody, S., and Procter, R. C., "Energetic efficiency of milk production and the influence of body weight thereon," Univ. Mo. Agr. Exp. Sta. Res. Bull. 222, 1935. Brody, S., and Cunningham, R., *Id.*, Res. Bull. 238, 1936.

duced milk at a gross energetic efficiency of 28 to 34 per cent; that is, 28 to 34 Cal milk were produced per 100 Cal TDN consumed. In other words, about $\frac{1}{3}$ of TDN energy consumed by the superior cows was recovered in the milk; or the TDN energy consumed was about 3 times the FCM energy produced.

Additional significant features of this table: (1) the daily FCM production was 10,000 to 17,000 Cal per day and TDN consumption 32,000 to 50,000 Cal per day; (2) the milk calories produced were from $1\frac{1}{2}$ to 2 times the estimated basal metabolism of the cows; (3) depending on the milk yield and efficiency, from $\frac{1}{3}$ to $\frac{1}{2}$ of the total TDN consumed was used for maintenance, leaving from $\frac{1}{3}$ to $\frac{2}{3}$ for milk production; (4) the cows consumed 2 to 3 times as much TDN during lactation as during non-lactating maintenance, a result in good agreement with the one previously cited for lactating rats and also for high-milking women.

The highest energetic efficiency of milk production that we encountered (estimated from the nomograph, Fig. 22.2) was 47.5 per cent for the Jersey champion cow Stonehurst Patrician's Lily, a 700-pound cow which produced 25,946 lbs FCM for the year. Much higher absolute production records were made, but at lower energetic efficiencies.

Thus the U. S. Holstein champion cow Carnation Ormsby Butter King "Daisy" produced¹⁴⁷ 36,476 lbs FCM per year, which is 40.5 per cent $\left(= \frac{36,476 - 25,946}{25,946} \times 100 \right)$

above that of the Jersey champion production; but since the Holstein cow weighed 1700 pounds, which is 143 per cent $\left(\frac{1700-700}{700} \times 100 \right)$ above that of the Jersey weight,

and since the Holstein cow probably used about 91 per cent $\left(= \frac{12.09 - 6.33}{6.33} \times 100 \right)$

more TDN for maintenance than the Jersey, the gross energetic efficiency of milk production of the Holstein was computed (from Fig. 22.2) to be only 43.5 per cent in contrast to gross efficiency of the Jersey of 47.5 per cent. This 47.5 per cent gross efficiency value with regard to TDN is probably near the limit of biological possibility. The detailed production records of "Daisy" are given in the following table.

Production Records of Carnation's "Daisy"

Lactation month	FCM (4% milk), lbs./day	FCM, Calories/day	Estimated gross energetic efficiency
1	97.38	33109	43.8
2	105.61	35907	44.6
3	103.16	35074	44.4
4	110.51	37573	45.3
5	107.68	36611	44.9
6	102.85	34969	44.3
7	102.94	35000	44.3
8	97.15	33031	43.7
9	96.31	32745	43.6
10	91.89	31243	42.9
11	90.01	30603	42.7
12	91.18	31001	42.9

It is significant that the gross energetic efficiency of milk production of "good" dairy cows is of the same order as the gross efficiency of early postnatal growth on "good" diets, namely about 30 per cent (Ch. 3). Thus chicks and cattle grow at, roughly, the same gross energetic efficiency in early postnatal life, just as large and small cows tend to produce milk with equal gross energetic efficiency.

¹⁴⁷ See *Holstein-Friesian World*, Feb. 22, 1936.

It will be presently shown that the *net* energetic efficiency of milk production with respect to TDN consumption in dairy cattle is of the order of 60 per cent. Since *net* efficiency does not include maintenance cost, therefore *gross* efficiency, which does include maintenance cost, can never reach the net-efficiency of 60 per cent level; 50% is probably as high a gross efficiency level with respect to TDN consumption as it is possible to achieve.

21.6.2: Gross efficiency of milk production in dairy goats. The efficiencies of seven goats were investigated¹⁴⁸. Their weights averaged 42.5 kg (93.5 lbs); daily milk production 2114 Cal, or 6.2 lbs FCM; gross efficiency of milk production with respect to TDN ranged from 32 to 40 per cent, averaging 34.9 per cent. The conclusion follows that the gross energetic efficiency of milk production in dairy goats is of the same order as that of dairy cattle.

It is significant that women, in the same weight class with goats, produce milk at the same level and at the same gross efficiency as goats. Thus wet nurses were reported to produce 4.5 liters (about 10 lbs) per day¹⁴⁹, and 3.1 liters (near 7 lb or 2100 Cal) milk per day¹⁵⁰. These women¹⁵⁰ converted 30 to 50 per cent of the food calories to milk calories, confirming Hoobler¹⁵¹, who observed women converting from 41 to 47 per cent of their dietary calories into milk, that is, producing milk at a gross energetic efficiency of 41 to 47 per cent.

21.6.3: Gross efficiency of milk production in rats. There is some difficulty in obtaining the milk-energy production in rats. However, we¹⁵² are confident of the following results because they represent concordant values obtained by two methods as follows:

(A) The milk produced in the rat was estimated from the weight gains of the litter during timed suckling intervals, corrected for weight losses due to urination, defecation, and insensible perspiration:

$$\text{Gross efficiency of milk production in the rat} = \frac{\text{Gain in litter weight (gm) during suckling plus loss in litter weight due to insensible perspiration} \times \text{Calories per gm rat milk}}{\text{Calories TDN consumed by mother}} \quad (\text{A})$$

The caloric value of rat milk was estimated from its composition. We assumed, on the basis of data by Mayer¹⁵³, and by Cox¹⁵⁴, that rat milk contains 16 per cent fat, 12 per cent protein, 3 per cent carbohydrate; therefore, a gram of rat milk has a combustion value of 2.3 Cal ($9.5 \times 0.16 + 5.6 \times 0.12 + 0.03 \times 4 = 2.3$).

(B) The milk produced in the rats was also estimated from the energy stored in the litter, plus maintenance of the litter.

Fig. 21.12a. Milk production and energetic efficiency of milk production in rats in relation to stage of lactation, litter size, litter weight, food intake of mother rat, and litter metabolism. The energetic efficiency of milk production was obtained by two methods, method A (Fig. 21.12a), method B (Fig. 21.12b), and by both methods, A and B (Fig. 21.12c). Note that the rats produced 15 to 115 Cal. (av. 60 Cal.) milk per day, and 700-1400 Calories during the 21-day lactation period; that the mother rats consumed 70-220 Cal. TDN per day, depending on litter size (milk production). The numbers in parenthesis represent number of rats in litter. Fig. 21.12c compares the results obtained by methods A and B directly. Note that method A yields lower values than method B on animals A in the early stages of lactation, and higher values in the late stages. This discrepancy is due to: 1) increasing fuel value of the weight gains of the litter with increasing age, while in computing results it was assumed that the fuel value per gram gain is constant; 2) decreasing fuel value per gram milk with increasing milk production, while in computing results it was assumed that the fuel value per gram milk is constant.

Fig. 21.12b. See legend for Fig. 21.12a.

$$\text{Gross efficiency of milk secretion in the rat} = \frac{\text{Energy stored in the litter} + \text{maintenance cost of litter}}{\text{Calories TDN consumed by mother}} \quad (\text{B})$$

The maintenance cost was estimated from the respiratory exchange (heat production); the stored energy, by multiplying the weight gains in grams by 1.5, assuming that 1 gm. body weight gain is equivalent to 1.5 Calories.

Fig. 21.12a to c present the results on milk production, and energetic efficiency of the rat as obtained by methods (A) and (B) above.

Fig. 21.12c. See legend for Fig. 21.12a.

The gross efficiency of milk production in the rat, in the flush of lactation, between the 10th and 18th, is seen from Fig. 21.12 to be between 44 and 48 per cent, which is of the same order as in the *champion* cows. The milk-production efficiency of the rat is higher than that of the *average-superior* experiment station cows, perhaps because the rats were on a relatively better (high-milk cereal) diet than the cattle (grain-hay); or perhaps because rats—raising large litters in a few days—are lactationally superior to cattle—raising 1 calf during a relatively long period. The important fact is that the gross energetic efficiency of milk production in the rat during the flush of lactation is of the same *order* as in cows or goats.

21.6.4: Influence of body size on gross efficiency of milk production. It is said that large animals are better milk producers than small ones because,

as a rule, they produce more milk¹⁸⁵. It is also said that small animals are better milk producers than large because (other conditions being equal) small animals produce more milk *per unit body weight* than large. Thus, as explained above, the average milk Calories produced per kg body weight are about 175 for rats and 25 for dairy cows.

However, the comparison of milk production in the preceding section shows that the *energetic efficiency* of milk production (the ratio of milk energy pro-

Fig. 21.13. Milk (FCM) production as function of body weight of 2-year old, 3-year old . . . Jersey cattle. Data compiled and averaged from the *Jersey Register of Merit* yearbooks 1918, 1920, and classified by ages as follows: 849 records, age 23-25 months (2 yrs.); 338 records, age 35-7 mos. (3 yrs.); 304 records, age 47-47 mos. (4 yrs.); 245 records ages 59-61 mos. (5 yrs.); 581 records 6-8 yrs.; 449 records 6-8 yrs., re-entries; 191 records 8-10 yrs., re-entries.

duced to food energy consumed, or "dairy merit") is virtually the same in rats, goats, humans, and cattle. We thus conclude that differences of opinion concerning the influence of body size on milk production are due to differences

¹⁸⁵ Cf. McDowell, J. C., U. S. Dept. Agr. Cir. 114, 1930. According to dairy-cattle herd-improvement association data, there is an increase in yearly yield of approximately 10 lb butterfat or 250 lbs FCM per 100 lbs increase in live weight. Under official-test conditions, there is an increase of about 20 lbs butterfat or 500 lbs FCM for each 100-lb increase in body weight.

in the reference bases employed (Ch. 13). The fact is that when other conditions are equal, a large animal produces more milk *per animal* than a small animal; a small animal produces more milk *per unit weight* than a large animal; large and small animals produce the same amounts of milk energy *per unit food energy*. This problem of influence of body size on milk production, with special reference to practical (monetary) implications, is discussed in the following chapter (Sects. 22.2, 22.3, and Table 22.1).

Figs. 21.14a. Milk (FCM) production on lower curves and gross efficiency of milk production on upper curves. Fig. 14a represents the 243 experiment station cows listed in the table at the end of this chapter; the other curves are also plotted from the same table, as indicated. While FCM production usually rises with increasing body weight, efficiency usually declines. Further details are given in Univ. Missouri Res. Bulls., 222, 238, 239.

Small dairy cows are frequently more efficient energetically than large ones (Fig. 21.13 and 14). This is not due to body size *as such* but because the basis for selection has been the production *per cow*. To stay in the herd the small cow has had to produce nearly as much as the big one; but if the small cow produces as much as the big cow, she is more efficient because she has a smaller body and maintenance and therefore expends less of her feed for maintenance.

Figs. 21.13 and 21.14 also show how milk production tends to rise with body weight in cattle. This problem is discussed in Chapters 13 and 22.

It thus appears from the above analysis of lactation data of cattle, goats, rats, and humans that body size *as such* does not influence the energetic effi-

Fig. 21.14b. See legend for Fig. 21.14a.

Fig. 21.14c. See legend for Fig. 21.14a.

ciency of milk production; other conditions being equal, small and large animals convert the same percentage of food energy into milk energy.

The gross efficiency of milk production of good dairy cattle with respect to TDN energy consumed¹⁵⁶ is of the order of 30 per cent. However, it appears from indirect evidence that at the biologic limit, that is, in the highest-producing champions, the gross efficiency may rise to 50 per cent. Following the psychologist's I.Q. (intelligence quotient) concept we may say that if the gross efficiency of milk production of the "average good" cow is 30 percent, and if a given champion cow's gross efficiency is 50 per cent, the L.Q. (lactation quotient) of the champion cow is $48/30 = 160$. A cow having a L.Q. of 166 is a "lactational genius", just as a man having an I.Q. of 166 is an "intellectual genius".

21.6.5: Net efficiency of milk production. Having found that the average gross efficiency (including maintenance cost) of milk production of good dairy cattle is of the order of 30 per cent and of champion cows, at the biologic limit near 50 per cent, we next proceed to investigate the *net* energetic efficiency (excluding maintenance cost) of milk production. It is true that from the economic viewpoint the overall or gross efficiency is the more important; but we shall see that the net efficiency is also of considerable interest.

It was previously noted that the net efficiency of milk production with respect to TDN consumption is of the order of 60 per cent. The following discussion indicates how this value was obtained.

To evaluate the net efficiency, it is necessary to determine how much of the consumed TDN is used for (1) producing milk, (2) maintaining the animal, (3) gaining (or losing) body weight.

The partition of the feed for its various uses is evidently a problem of great difficulty. This cannot be done by a direct experimental approach. Accordingly, we devised an indirect statistical approach as follows¹⁴⁶.

Assume that the TDN is used for only the three purposes: producing milk, maintaining the cow, and gaining weight; and write this statement in the form of an equation:

$$TDN = B(FCM) + C(W^{0.73}) + D\Delta(W) \quad (21.4)$$

in which TDN = total digestible nutrients consumed; FCM = 4 per cent milk produced; $W^{0.73}$ = live weight raised to the 0.73 power; ΔW = gain or loss in body weight. When other variables are held constant, B and D represent, respectively, units of TDN required to produce unit of 4 per cent milk, FCM , and to gain unit live weight, ΔW . The TDN cost of maintenance is C times body weight raised to the 0.73 power.

Then fit the equation to the data by the method of least squares, that is, by minimizing the squares of the residuals with respect to the three constants, B , C , D . This we did to the yearly lactation records of the 243 experiment station (Table 21.5) Holstein and Jersey (and a few Guernsey) cows 5 years of age or over (to eliminate age com-

¹⁵⁶ The gross efficiency would be less if related to the gross instead of digestible energy consumed. Thus E. B. Forbes and A. Le Roy Voris, [*J. Nut.*, **5**, 395 (1932)] observed a gross efficiency of milk production of 18–23% when related to the gross energy of the ration.

plications). The energies expended for converting milk precursors into milk and for the process of secretion are lumped with the *FCM* term. Solving in terms of pounds per day we obtain

$$TDN = 0.305FCM + 0.053 W^{0.73} + 2.1\Delta W \quad (21.4a)$$

The meaning of the constants is as follows: if maintenance and weight-gain costs are held constant, 0.305 lb *TDN* is used per pound *FCM* produced; if milk yield and maintenance costs are held constant, 2.1 lbs *TDN* are used for 1 lb gain in live weight; if milk yield and weight gain costs are held constant, the *TDN* cost of maintenance is 0.053 time weight raised to the 0.73 power.

Note that equation (21.4) is based on the following unproved assumptions: *TDN* for *FCM* varies linearly with *FCM* production¹⁸⁷; *TDN* for weight gain varies linearly with weight gain; *TDN* for maintenance is a power function, the power being 0.73, of body weight (so assumed because basal metabolism of mature animals of different species varies with the 0.73 power of body weight as explained in Ch. 13); *TDN* consumed is the algebraic sum of the above three terms—and no others.

The last assumption, that *TDN* consumption was not affected by factors other than *FCM*, *W*, and ΔW , may be tested by adding another constant, *A*, to take up the other unknown influencing factors, as indicated by the equation

$$TDN = A + B(FCM) + C(W^{0.73}) + D\Delta W \quad (21.5)$$

Solving, we obtained

$$TDN = 0.478 + 0.303 (FCM) + 0.051 W^{0.73} + 2.18\Delta W \quad (21.5a)$$

Inspection of eq. (21.5a) shows that the value of *A*, that is, 0.478 lb *TDN*, is small in comparison to the total *TDN* consumed by a lactating cow (av. for the 243 cows, 17.6 lbs *TDN*); moreover, the values of *B*, *C*, and *D* are inappreciably affected by omitting *A* (from 0.305 to 0.303 for *B*; from 0.053 to 0.051 for *C*; from 2.1 to 2.18 for *D*). Furthermore, the values of the statistical constants are very satisfactory for eq. (21.4).

From equation (21.4a) it is clear that if the overhead maintenance cost is not included, 0.305 lb *TDN*, or 553 Cal ($0.305 \times 1814 = 553$), are on the average used to produce 1 lb, or 340 Cal, *FCM*. The ratio of 340, the Cal in 1 lb *FCM*, to 553, the Cal in the *TDN* required to produce 1 lb *FCM*, that is, 0.61 or 61 per cent, is the *net* efficiency of milk production; it is the efficiency of converting *TDN* into milk, apart from the maintenance cost.

Gaines¹⁸⁸, employing a different approach, found that *B* = 0.305, exactly the same value as found by us. For maintenance, however, he found the second term of our equation (21.4a) to be not $0.05 W^{0.73}$, as we found, but $0.129 W^{0.60}$ "which two equations give the same results . . . when *W* = 937, and do not differ by more than 8 per cent at other values of *W* from 600 to 1800 lbs." "Furthermore, there is little choice between *n* = 0.60 and *n* = 0.73; while *n* = 0.73 is distinctly indicated in preference to *n* = 1.00. The lumped data, therefore, support the validity of Brody and Procter's working exponent 0.73 in preference to Haecker's exponent 1.00, or Morrison's exponent 0.87.

¹⁸⁷ In the original report (Univ. Mo. Agr. Exp. Sta. Res. Bull. 238, pp. 47-9) an attempt was made to evaluate the exponent *n* in the equation

$$TDN'' = B(FCM)^n$$

in which *TDN''* is total *TDN* consumed, less *TDN* used for maintenance ($CW^{0.73}$) and for weight gain ($D\Delta W$). The numerical value of *n* ranged from 1.5 for low-producing groups of cows to 0.34 for high-producing groups of cows. The interested reader is referred to this bulletin, and more especially to Gaines, W. L., *J. Dairy Sci.*, **20**, 583 (1937).

¹⁸⁸ Gaines, W. L., *J. Dairy Sci.*, **20**, 583 (1937), and **21**, 645 (1938).

When we examine the similar data for various subgroups, great confusion develops.¹⁵⁹ This confusion led Gaines to an examination of the maintenance feeding standards shown in Fig. 15.3, to suggest that "perhaps some factor not closely associated with live weight plays a prominent part" and to decide that for the present both, *FCM* production and maintenance *TDN* consumption, should be related to simple body weight, *W*, rather than to a fractional power, *n*, of body weight. He suggested using the Haecker milk-production feeding standard modified to $TDN = 0.3FCM + 0.008 W$, in which *FCM* is 4 per cent milk and *W* live weight, all in pounds, as contrasted to the present author's feeding standard $TDN = 0.305FCM + 0.053 W^{0.73}$. There is obviously no appreciable difference between the two for average-sized cows (about 1000 lbs). The differences concern only extremely small and extremely large cows and only as they relate to maintenance, not to milk production.

The values in equation (21.4a) may be used for computing the net efficiency of milk production.

The net efficiency term may be isolated from the gross-efficiency equation,

$$\text{Gross efficiency} = \frac{340 \times FCM \text{ (lbs)}}{1814 \times TDN \text{ (lbs)}} \quad (21.3a)$$

by remembering that the denominator includes: (1) *TDN* expense of maintenance, represented in eq. (21.4a) by $0.053 W^{0.73}$; and (2) weight gain, represented in eq. (21.4a) by $2.1\Delta W$. On substituting (1) and (2) from eq. (21.4a), we obtain:

$$\begin{aligned} \text{Gross efficiency} &= \frac{340FCM}{1814 (0.305FCM + 0.053W^{0.73} + 2.1\Delta W)} \\ &= \frac{340FCM}{553FCM + 96.1W^{0.73} + 3700\Delta W} \end{aligned}$$

Dividing the numerator and denominator by 553 (the *TDN* calories required to produce 1 lb *FCM*) presents net efficiency, 0.61, as a separate term in the gross efficiency equation

$$\text{Gross efficiency} = 0.61 \frac{FCM}{FCM + 0.173W^{0.73} + 6.64\Delta W}$$

which is similar to Gaines' "coefficient of efficiency",¹⁶⁰

$$\text{C. E.} = 52.6 \frac{FCM}{FCM + 8.47W}$$

The net-efficiency equation

$$\begin{aligned} \text{Net efficiency} \\ \text{of milk production} &= \frac{\text{milk calories produced}}{TDN \text{ calories consumed less maintenance}} \quad (21.2) \end{aligned}$$

may also be written by substituting the values of eq. (21.4a) into it, as follows:

$$\text{Net efficiency} = \frac{340FCM}{1814 [TDN - (0.053W^{0.73} + 2.1\Delta W)]}$$

The 61 per cent net-efficiency level is, of course, only a statistical average, for the given conditions, computed by the given method, and not applicable to an individual cow.

The detailed method of solving the partition equation (21.4) is shown in the appendix to this chapter. The numerical data for the individual cows are also listed in the appendix (Table 21.7).

¹⁵⁹ Gaines, W. L., *Science*, 67, 353 (1928).

Summarizing, this section presents a statistical method for partitioning the *TDN* consumed between maintenance, milk production and body weight gain, and computing therefrom net efficiency of milk production with respect to *TDN* consumption. It must be emphasized that the numerical value of the net efficiency would be much less if it were computed with respect to the gross energy of the feed; and much higher if it were computed with respect to metabolizable energy, and still higher—perhaps 90 or 95 per cent as found by Graham (previously discussed)—if it were computed with respect to net energy or to the milk-precursor energy entering the mammary gland.

It is evident that the *gross* energetic efficiency of milk secretion, which carries the burden of the maintenance cost of the cow, can never be as great as the *net* efficiency, which is not thus burdened with maintenance taxes. As production increases, the maintenance tax per unit milk produced becomes less and less; therefore, the gross efficiency approaches nearer and nearer to the net efficiency level, but at *decreasing increments*, in accordance with the law of diminishing returns. The relation between gross efficiency and milk production (FCM) level is shown in Fig. 1.2 (Ch. 1). Since the net efficiency of milk production is of the order of 60 per cent, the gross efficiency can never reach 60 per cent, but it may approach 50 per cent. This checks with the estimated gross efficiency for the 700-lb Jersey champion cow Stonehurst Patrician's Lily, previously cited.

21.7: Summary. This chapter discusses the following problems.

(1) The dairy industry and its place in the national, especially agricultural, economy. Dairy husbandry is the largest branch of agriculture from the viewpoint of return to the farmer and number of persons employed.

(2) The unique composition of milk, most conspicuously its lactose, casein, short-chain fatty acids, minerals, especially calcium and vitamins. The composition of milk is loosely related to the percentage growth rate or maturation rate of the body.

(3) The unique composition of milk is associated with its unique nutritional properties. Milk was evolved especially for the nutrition of young mammals and has a matchless combination of protein of high biologic value, of calcium, phosphorus and vitamins. It is poor, however, in iron, copper, manganese, and apparently magnesium. Milk happens to supplement almost perfectly whole-cereal diets for adult humans. Almost $\frac{1}{3}$ of the dietary energy consumed in this country in "adequate" and "liberal" diets comes from milk. The skim-milk-butter-margarine problem is discussed in some detail.

(4) From the viewpoint of relative energetic economy of meat, egg, and milk production, the gross efficiency of *early* growth and of average milk production is of the same order. As, however, the animal increases in size, its efficiency for meat production decreases rapidly because of the mounting maintenance cost in comparison to the growth increments. Moreover, much of the animal body is inedible, whereas all of milk is edible. Furthermore, with the exception of some visceral organs, as liver and kidney, milk has unique supplementary properties not found in meat. Finally, the possibility of in-

creasing the energetic efficiency of milk production (by improved breeding methods) is greater than for meat production. In general, the gross *energetic* efficiency of milk production tends to be about twice that of egg production and about five-fold that of meat production (Ch. 3).

(5) Physico-chemical considerations of milk production indicate complex interdependence between osmotic and enzymatic factors and between the protein, fat, lactose, and water constituents. Milk sugar is produced not only from blood sugar, but also from blood lactic acid and from amino acids. Milk fat is derived mostly from blood fat, and milk protein from blood protein and amino acids.

(6) It is shown that there is a considerable heat increment of lactation. It is not possible to measure the *basal* metabolism of lactation because the post-absorptive condition requisite for basal metabolism depresses the milk flow so that lactation is no longer normal.

(7) It is shown that good experiment-station dairy cattle (for example, 1100-lb cows producing about 35 lbs FCM per day and consuming 21 lb TDN per day) produce milk at a gross energetic efficiency near 33 per cent with respect to TDN consumed, that is, about one-third of the TDN fed a good cow is recovered in the milk. By proper breeding, the gross efficiency may be increased to a maximum near 50 per cent. The *net* efficiency of milk production (not counting the maintenance cost) with respect to TDN consumption is shown to be of the order of 60 per cent.

(8) The gross energetic efficiency of milk production is apparently independent of live weight as such. It is true that the ratio of milk-energy yield to body weight is greater in small animals, such as 120-lb goats, than in large animals such as 1200-lb cows; but the ratio maintenance-energy cost to body weight is likewise greater for the 120-lb goat than for the 1200-lb cow, with the net result that the extra maintenance cost counterbalances the extra milk yield and the gross efficiency is unaffected by body size.

(9) The appendix indicates the method for fitting the "partition equation," partitioning the food consumption between maintenance, milk production, and body gain; and presents numerical data on milk production, feed consumption, body weight, and related items.

Appendix: Estimating the amounts of consumed TDN used for FCM production, maintenance, and weight gain (solution of eq. (21.4a)). The partition of the consumed TDN between its uses for each, FCM, maintenance ($W^{.73}$), and weight gain (ΔW), may be carried out graphically, or algebraically by the method of least squares.

The graphic method consists in plotting TDN successively against each of the independent variables, namely FCM, $W^{.73}$, and ΔW ; correcting observed TDN values for the influence of one variable by approximating TDN cost per unit of that variable; subtracting computed TDN required for the one variable from the observed TDN for each datum; correlating corrected TDN with another variable and determining a second correction. These first approximations of the parameters are improved by successively repeating this process of approximation until the sum of the squares of the differences between observed and computed TDN is minimum.

The least-squares method eliminates the laborious successive approximations. The solution of the partition equation

$$TDN = B(FCM) + CW^{.73} + \Delta W \quad (21.4)$$

by the least-squares method involves substituting in three "normal equations" simultaneously, and weighting the trends of TDN with FCM , W , and ΔW so as to give at once a minimum value for the sum of the squares of the differences.

An obvious objection to equation (21.4) is that it was formulated on the assumption that the milk secretion, maintenance, and weight-gain factors are independent. This is by no means certain. Moreover, since the coefficients in the equation are computed by the method of least squares, it is clear that if the value of one coefficient is too high due to some experimental or biological situation, the values of the other coefficients will be influenced thereby. Each of the terms represented in equation (21.4) has its separate set of experimental errors and biological variations. When combined into one interrelated system, each of these terms influences the value of every other term. There consequently results a very complex system of interinfluencing relationship.

A large population compensates and smoothes out individual experimental errors and biological variations so that dependable average values for the equation constants B , C , and D result. But if a small population is combined with large errors and variations, the equation constants are no longer dependable, and are often absurd, as illustrated by the following numerical examples.

The aforementioned three "normal equations" for equation (21.4) are:

$$\Sigma(TDN)(FCM) = B\Sigma(FCM)^2 + C\Sigma(FCM)(W^{.73}) + D\Sigma(FCM)(\Delta W)$$

$$\Sigma(TDN)(W^{.73}) = B\Sigma(FCM)(W^{.73}) + C\Sigma(W^{.73})^2 + D\Sigma(W^{.73})(\Delta W)$$

$$\Sigma(TDN)(\Delta W) = B\Sigma(FCM)(\Delta W) + C\Sigma(W^{.73})(\Delta W) + D\Sigma(\Delta W)^2$$

Taking, by way of illustration, the data for the 15 World's Fair Holsteins listed in Table 21.6, we obtain the following summations:

$$\begin{array}{ll} \Sigma(TDN)(FCM) = 19525.1508 & \Sigma(FCM)(\Delta W) = 593.90690 \\ \Sigma(TDN)(W^{.73}) = 74486.866 & \Sigma(W^{.73})^2 = 522017.86 \\ \Sigma(TDN)(\Delta W) = 327.95458 & \Sigma(W^{.73})(\Delta W) = 2303.8917 \\ \Sigma(FCM)^2 = 36129.7151 & \Sigma(\Delta W)^2 = 11.251476 \\ \Sigma(FCM)(W^{.73}) = 136482.688 & \Sigma(TDN)^2 = 10642.4553 \end{array}$$

Substituting in the "normal equations" we have:

$$\begin{array}{rclcl} 1952.1508 & = & B \ 36129.7151 & + & C \ 136482.688 & + & D \ 593.90690 \\ 74486.866 & = & B \ 136482.688 & + & C \ 522017.86 & + & D \ 2303.8917 \\ 327.95458 & = & B \ 593.90690 & + & C \ 2303.8917 & + & D \ 11.251476 \end{array}$$

Solving these equations we obtain $B = 0.11642$, $C = 0.11146$, and $D = 0.18040$, i.e., $TDN = 0.116 FCM + 0.11W^{.73} + 0.180\Delta W$. Illustrating the solution by Doolittle's method¹⁶⁰ we have:

Line Reciprocals	B	C	D	—	Sum
I	36129.7151	136482.688	593.90690	-19525.1508	153581.15920

		B = .116418411			

¹⁶⁰ See Ezekiel, M., "Method of correlation analysis," New York, 1930, Ch. 12. See also, Mills, F. C., "Statistical methods applied to economics and business," New York, 1924, p. 577.

The standard error of estimate for equation (21.4a) is

$$S_r^2 = \frac{(TDN)^2 - B(TDN)(FCM) - C\Sigma(TDN)(W^{0.75}) - D\Sigma(TDN)(\Delta W)}{N}$$

where N is the "degree of freedom." The "degrees of freedom" is the number of data points less the number of arbitrary constants in the equation fitted; thus $N = 15 - 3 = 12$.

Substituting:

$$S_r^2 = \frac{10642.4553 - (.11642 \times 19525.1508) - (.11146 \times 74486.866) - (.18040 \times 327.95458)}{12}$$

$$S_r^2 = \frac{10642.4553 - 2273.1181 - 8302.3061 - 59.1630}{12} = \frac{7.8681}{12}$$

$$S_r^2 = 0.655675$$

$$S_r = 0.810$$

The standard error of estimate, $S_r = 0.81$, means that two-thirds of the time the TDN computed from this equation will agree with the observed TDN consumption within ± 0.81 lb.

This small value of S_r leads one to think that the numerical values of B , C , and D are significant and reliable. As a matter of fact these values are so far out of line that they must be considered meaningless. Thus the maintenance of a 1000-lb cow is, according to this equation, $0.1115 \times 1000^{.75} = 17$ lbs, which is over twice the Morrison allowance of 7.9 lbs, and therefore absurd. The net efficiency is, according to this equation, $\frac{340 \times 100}{.1164 \times 1814} = 164$ per cent, which is of course impossible. In other words, of the available TDN , far too much is apportioned by this equation to maintenance, and far too little for milk production (and for weight gain).

Does this mean that equation (21.4) is wrong? Not necessarily. It means that the number of animals in the population is too small in comparison to the variability. The data points are too irregular and too few to give the equation a lead, so to speak, to the real situation. The three sets of guide posts involved in showing the road (TDN trends for FCM production, maintenance, weight gain) are so few, and distributed so erratically, that they are blurred and therefore useless as guides for reaching the desired goal.

It is not the fewness of the data that is alone responsible for the erratic results, as the combination of fewness, limited range, and erratic distribution of data. The erratic distribution of the data is probably due to their experimental errors. Better (even if fewer) data give better results. Thus equation (21.4) fitted to only 10 of the Pennsylvania Animal Nutrition Institute (Forbes) data gave entirely satisfactory results. In this case the value of C for equation (21.4) was found to be 0.053, so that the maintenance for a 1000-lb cow is 8.2 lbs (which is the average of the value found for the 243 Experiment Station cows (Fig. 21.14a); the value of B was found to be 0.292, indicating net efficiency of 64 per cent (in comparison to 61 per cent found for the 243 experiment Station cows). This brings us back to the statement that reliability of the equation parameters is conditioned on accuracy of the data. To summarize, equation 21.4 gives dependable average values separately, for FCM production, maintenance, weight-gain but only provided that the population is reasonably large and the data are reliable.

TABLE 21.1. COMPARISON OF THE NATIONAL RESEARCH COUNCIL (1943) NUTRITIONAL-NEED STANDARD FOR A 70-KG MODERATELY ACTIVE MAN WITH THE NUTRIENTS SUPPLIED BY ONE QUART OF RAW MILK.

Nutrients	Average daily requirement for a 70-Kg, (154-lb) adult	Amount in one quart milk	Approximate portion of the daily requirement supplied by one quart raw milk
Protein (gm)	70	34	$\frac{1}{2}$
Calories	3000	675	$\frac{1}{4}$
Calcium (gm)	0.8	1.16	$1\frac{1}{2}$
Phosphorus (gm)	1.3	0.91	$\frac{1}{2}$
Iron (mg)	12	1.94	$\frac{1}{2}$
Vitamin A ¹² (I.U.)	5000	1900	$\frac{1}{2}$
Vitamin D ¹² (I.U.)	400	25	$\frac{1}{16}$
Ascorbic acid ¹³ (mg)	75	19.4	$\frac{1}{4}$
Thiamine (mg)	1.8	0.28	$\frac{1}{6}$
Nicotinic acid (mg)	18	1.1	$\frac{1}{16}$
Riboflavin (mg)	2.7	1.7	$\frac{2}{3}$

The Calories in milk are divided equally between fat and non-fat fractions:

Constituent	Grams/quart	Calories/quart
Fat	37	333
Lactose	49	196
Protein	34	136
		332

TABLE 21.2 FATTY ACID COMPOSITION OF FAT IN MILK AND BEEF PLASMA.

Saturated acids	Carbons	Percentage by weight in:	
		milk	beef plasma
Butyric	4	3.7	
Caproic	6	2.0	
Caprylic	8	1.0	
Capric	10	2.6	
Lauric	12	1.7	
Myristic	14	8.3	0.4
Palmitic	16	25.4	24.5
Stearic	18	10.7	12.3
Arachidic	20	0.4	0.8
Unsaturated acids			
Deconic	10	0.2	
Tetradecenoic	14	1.2	
Hexadecenoic	16	5.0	2.5 (Palmitoleic)
Oleic	18	32.4	17.4
Octadecenoic	18	4.0	
C 20 to 22 unsat.	20-22	0.4	1.3 (Arachidenic)
Linoleic			36.5
Linolenic			4.2

TABLE 21.3 COMPOSITION OF MILK OF DIFFERENT SPECIES AND GROWTH RATE.
(After Abderhalden, modified, enlarged with averaged data from various sources and percentage-distribution sections added.)

Species	Growth rate (days for doubling body weight)	Constituents as percentages of whole milk						Constituents as percentages of milk solids				Caloric values of constituents as percentages of caloric values of milk			Fuel value Cal/gm
		Fat	Protein	Lactose	Ash	Water	Total solids	Fat	Protein	Lactose	Ash	Fat	Protein	Lactose	
Cow	70 (47)	4.4	3.8	4.9	0.7	86.2	13.8	32	27	36	5.1	53	20	26	.75*

Chapter 22

The Monetary Economy of Milk Production

The dairy farmer would be very glad indeed to function more abundantly in the support of national health if an economic framework could be devised.

H. D. Kay

The overall monetary economy of milk production—including cost of human labor—depends on many factors, of which the milk-production level per animal is most important. The latter may be raised by increasing (1) “dairy merit”, (2) body size, and (3) plane of nutrition. We shall define and indicate the bearing of each on the monetary economy of milk production.

22.1: “Dairy merit”: quantitative definition. The designation “dairy merit” is related to the economy of milk production, but the relation is not clear; it means different things to different dairymen. Let us, therefore, define it quantitatively by saying that “dairy merit” represents the biological efficiency of milk production as measured by the percentage of consumed *TDN* energy which is converted into milk (*FCM*) energy. This definition may be represented by the equation

$$\text{Dairy merit} = \frac{\text{milk-energy production}}{\text{TDN-energy consumption}} = \frac{340 \times \text{lb } FCM \text{ produced}}{1814 \times \text{lb } TDN \text{ consumed}} \quad (1)$$

assuming that 1 lb *FCM* (“fat-corrected milk”, milk containing 4 per cent fat) has an energy equivalent of 340 Calories, and 1 lb *TDN* (total digestible nutrients) has an energy equivalent of 1814 Calories. Dairy merit of the *animal* is numerically equal to the gross energetic efficiency of the lactation *process* (Chs. 1, 3, 21).

The upper limiting value of this dairy-merit ratio is 50 per cent; not over one-half of the consumed *TDN* energy can be converted into milk energy. Superior dairy animals convert about one-third of the consumed *TDN* energy into milk energy; good dairy animals, about one-fourth.¹ A 25 per cent dairy-merit level pays, approximately, for the dairyman’s work, feed, and other expenses at the current rate. Really profitable milk production involves higher dairy merit.

The dairy merit, or efficiency, of a given animal is, of course, dependent on her milk-production level.

The average milk-production level in the United States is about 4500 lbs milk or 160 lbs butterfat per cow per year. This yield is about one-tenth of the upper lactational

¹ Brody, S., *J. Nut.*, 17, 235 (1939); *Science*, 95, 485 (1942); Univ. Mo. Agr. Exp. Sta. Res. Bull. 366, 1943.

performance of cattle. A cow recently produced 42,000 lbs milk (about 1400 lb butterfat) in a year², and the writer believes, on the basis of considerations to be explained presently, that the potential upper lactational performance for dairy cattle is nearer 50,000 lbs *FCM* or 2,000 lbs butterfat a year.

It is theoretically simple to double the average milk production of 4500 lbs milk, or 160 lbs butterfat a year by the use of well-bred sires. The simplicity is indicated in the following table.³

Sire used	Production, lbs/year					
	Original cows		First generation daughters		Second generation daughters	
	Milk	Fat	Milk	Fat	Milk	Fat
Guernsey.....	4,480	202	5,729	253	7,155	355
Holstein.....	3,631	176	6,649	278	10,218	395
Jersey.....	4,047	194	5,015	270	6,539	331
Average.....	4,110	192	5,815	267	8,056	363

The Dairy-Herd Improvement Association cattle currently produce from 8,000 to 10,000 lbs *FCM* (milk corrected to 4% fat) a year. The dairy cattle in Denmark produced, on the average, about 7500 lbs milk a year. On the other hand, the average productive level in Great Britain, Canada, and New Zealand is no better than in the United States, 4,000 to 5,000 lbs a year. These countries thus fail to make use of their dairy potentialities. They could easily double the milk production with the same cattle population.

The dairy industry is evidently capable of great expansion in production and income, easily doubling and potentially capable of tripling or quadrupling the present average production, without increasing the number of cows. The two outstanding needs are (1) a yardstick for *measuring dairy merit* of animals, *uncomplicated by differences in body size*; (2) a method for *predicting milking potentiality in young animals*. We attempted to correlate basal energy metabolism in the young with productive level in the adult. The difficulty in developing this, or any other, potentiality index is that it involves investigating large, unselected populations over many years, which is expensive. Just as methods have been developed for early recognition of intellectually gifted children,⁴ so methods will be developed for early recognition of lactationally gifted cattle. The economic saving that may result from an index of lactational potentiality is indicated by the fact that of the 6 million dairy heifers raised annually, only one-third turn out to be profitable.

Dairy merit appears to be independent of body size *as such*; its upper limiting value is approximately the same in rats, goats, cows, and even in humans.

² The 8-year old 1750-lb Carnation Ormsby Madcap Fayne, produced 41,943 lbs 3.33%-fat milk in a (365-day) year [Prescott, M. S., *Holstein-Friesian World*, **39**, 679 (1942)]. This is equivalent to an average of 115 lbs milk a day (at one time she produced 146 lbs milk in a day; 19,508 quarts milk a year (1 qt = 2.15 lbs); 1740 lbs butter (1 lb butterfat = 1.25 lbs butter); 1463 lbs protein, equivalent to 3775 lbs American cheese; 2034 lbs lactose; 285 lbs minerals containing 58 lbs calcium, 37 lbs phosphorus, and so on. At the rate of 1 quart milk a day, this would supply one person for 53½ years. The 8-year old 1700-lb cow Carnation Ormsby Butter King produced 38,607 lbs of 3.63% milk, 1402 lbs butterfat in a (365-day) year.

³ McCandlish, A. C., *et al.*, Iowa Exp. Sta. Bull. 251.

⁴ For early recognition of the intellectually gifted, see Terman, L. M., "Psychological approaches to the biography of genius." *Science*, **92**, 293 (1940).

Approximately the same percentage of digestible dietary nutrients consumed may be converted into milk in all these species, large or small.⁵ The profit on milk production, however, does vary with body size of the animal because, if other conditions are equal, the overhead expense per unit milk production declines with increasing size of animal. Let us, therefore, next define body size quantitatively.

22.2: Lactationally effective body size: quantitative definition. Since the feed is converted into milk by the body, the quantity of such conversion should, other conditions being equal, increase with the size of the body. Body size must be an important factor. It is true that some large cows yield no more, and often less, than small ones; but this is because the *dairy merit*, the lactational drive, of the large cow is inferior to that of the small one—because other conditions are not equal. Thus dairy cows produce more milk than beef cows of the same size because of *dairy merit* differences. But when other conditions are equal, a small dairy cow should yield more milk than a dairy goat; a large dairy cow should yield more than a small dairy cow. Since there is a maintenance cost for every pound of live weight, each pound necessarily counts for or against the dairy merit and profit of the animal yielding a given quantity of milk energy, depending on whether or not each pound produces milk in proportion to its maintenance cost.

The major reason for the general neglect of the body weight datum in reporting milk yield is that milk production does not increase *directly* with *simple* body weight but in a more complex manner, which appears to be confusing. For instance, we know of a 700-lb cow (Stonchurst Patrician's Lily)⁶ that produced at the rate of 70 lbs *FCM* a day, or 26,000 lbs *FCM* a year, but it is probably impossible for 1400-lb cow to produce at the rate of 140 lbs *FCM* a day or 52,000 lbs *FCM* a year. Milk production evidently does not increase directly with simple weight. This gives the superficial impression that body weight may not be an important factor in milk production, which is definitely not the case.

Milk is not produced by the body as a whole, but only by the visceral (internal) organs and by the surfaces that participate in the digestive, assimilatory, respiratory, excretory, and secretory (including endocrine) processes. The supporting structures (skeletal muscles and bones) do not participate in the milk-production process; and it so happens, for reasons previously explained (Ch. 17, also Ch. 13), that these non-participating supporting structures increase at a relatively more rapid rate, or the visceral and surface

⁵ There is no reason for assuming that different amounts of consumed feed energy, above the maintenance needs, should be required to produce unit milk energy in, for example, 700 and 1400-lb cows; there is no reason why the energy cost of producing unit milk above the maintenance cost, should be different in the two animals. If the maintenance cost is included, the efficiency will be the same if the ratio of milk-energy production to maintenance-energy cost is the same in large and small animals, and this appears to be the case.

⁶ *Jersey Bulletin and Dairy World*, 54, No. 15 (April 10, 1935).

structures increase at a relatively less rapid rate, than the body as a whole.

In other words, a 1200-lb cow cannot produce ten-fold the milk energy of a 120-lb goat at its upper limit, and a 1400-lb cow cannot produce twice the milk energy of a 700-lb cow at its upper limit, because large animals have relatively larger supporting structures and, therefore, relatively smaller visceral organs and areas than small animals (Ch. 17).

In an analysis of milk-energy production in relation to body weight in different species¹ (rats, goats, and cows), milk production was observed to vary with, approximately, the 0.7 power of body weight, or $W^{0.7}$ (Fig. 22.1a). This means that increasing body weight 1 per cent tends to cause an increase

Fig. 22.1a. The relation of milk-energy production to body weight in mature animals of different species: averages of 368 "good" cows, 7 good goats, 5 excellent rat mothers. Plotted on a logarithmic grid. Y represents milk-energy production per day for body weight, W.

in milk production of 0.7 per cent. More concretely, a 1400-lb cow tends to produce not 100 per cent more milk than a 700-lb cow, but only 70 per cent more, and this only when the dairy merits of the two cows are the same. The reference base $W^{0.7}$ is, of course, very close to that of $W^{2/3}$, the conventional reference base for the surface-weight relation ($S = aW^{2/3}$); so that one may say, if one prefers, that milk-energy production tends to vary directly with surface area.

Now, the basal energy metabolism and resting maintenance needs for energy and protein also vary with, approximately, $W^{0.7}$ (Chs. 13-15). It is true that the energy cost of moving the body during walking and similar activities varies directly with body weight, with $W^{1.0}$; however, voluntary activities of animals tend to decline with increasing body weight; large animals

are likely to make fewer and slower movements than small ones, and the decline appears to be in such manner that the total maintenance cost tends to vary with $W^{0.7}$, in the same manner as does milk-energy production (Ch. 15).

If, then, the maintenance-energy cost and the milk-energy production vary in the same manner with increasing body weight, dairy merit, *i.e.*, the ratio of milk-energy production to feed-energy consumption, must be the same in small and large animals⁵ and this is virtually demonstrated for rats, goats,

Table 22.1. Milk Production in Relation to Various Reference Bases in Cattle, Goats, and Rats

	Average of 368 "good" cows	Average of 7 "good" goats	Average of 12 "good" white rats	A "cham- pion" Hol- stein cow ¹	A "cham- pion" Jersey cow ²
Live weight, (lbs)	1,130	95	0.662	1,700	700
Live weight, (kg)	513	43	0.3	771	318

Ratio milk Cal per kg live weight	22	50	150	44	63
Ratio Milk Cal to estimated basal-met. Cal	1.7	1.9	2.1	3.8	5.1
Milk Cal per kg ^{0.70} live weight ³	145	152	139	324	428
Milk Cal per kg ^{0.73} live weight ⁴	120	137	147	266	360
Ratio <i>FCM</i> lbs to lb ^{0.7} live weight ⁵	24.5	25.6	23.6	54.8	72.4
Dairy merit = gross energetic efficiency ⁶	31%	34.9%	44%	44%	48%

¹ This 1700-lb cow, Carnation Ormsby Butter King "Daisy" [*Holstein-Friesian World*, 33 (Feb. 22, 1936)] produced in 365 days 38,607 lbs of 3.63%-fat milk containing 1402 lbs butterfat.

² This 700-lb cow, Stonehurst Patrician's Lily [*Jersey Bull. & Dairy World*, 54, No. 15 (April 10, 1935)] produced in 365 days 24,094 lbs of 4.5%-fat milk containing 1087 lbs butterfat.

³ The kg^{0.70} values are respectively: 78.9, 13.9, 0.4305, 105, 56.5.

⁴ The kg^{0.73} values are respectively: 95.1, 15.6, 0.4152, 128.1, 67.1.

⁵ The lb^{0.7} values are respectively: 137.1, 24.2, 0.7492, 182.5, 98.1.

⁶ Dairy merit of a 120-lb goat is 44% when producing 15 lb *FCM*/day; 47.5% when producing 20 lbs/day; 41% when producing 12 lbs *FCM*, 39% for 10 lbs, 40.5% for 11.2 lbs.

and cattle (Table 22.1). We thus reach the important conclusions that (1) if other conditions are equal, dairy merit is independent of body size; (2) milk-energy production, as maintenance cost, varies not with simple body weight, $W^{1.0}$, but with $W^{0.7}$. The *lactationally effective* body size is represented not by $W^{1.0}$ but by $W^{0.7}$.

22.3: Evaluation of dairy merit. *Dairy merit* is defined by the ratio of milk-energy production to *TDN*-energy consumption. It is easy to obtain the milk-energy production⁷ but difficult to obtain the *TDN*-energy consumption. Because of this difficulty indirect dairy-merit indices may be used.

⁷ Milk-energy production (according to Gaines) = 340 x lb *FCM*. *FCM* represents milk corrected to 4% fat. Table 22.3 lists factors and equations for converting milk of any fat percentage to *FCM*.

The dairy-merit index proposed by Gaines⁸ is the ratio of milk production to live weight, FCM/W , as for example, milk production per 1000 lb live weight.

The FCM/W dairy-merit index is the easiest to compute and to understand. It is, perhaps, satisfactory for comparing animals of nearly the same body weight, such as those within a homogeneous breed of cattle. But the FCM/W index is not satisfactory when animals differ widely in weight, as, for example, Carnation Ormsby Butter King Daisy and Stonehurst Patricians Lily (1700 lbs and 700 lbs, respectively). The 700-lb cow produced at the average rate of 70 lbs FCM a day, while it is probably physically impossible for a 1700-lb cow to produce $70 \times \frac{1700}{700} = 170$ lbs FCM a day.

The first three columns in Table 22.1 show that the ratio of milk Calories to simple body weight, kg, declines from 150 for rats to 50 for goats to 22 for cows; the FCM lbs per 1000 lbs body weight ratio declines from 267 for rats, to 66 for goats, to 30 for cows. On the other hand, the ratio of FCM lbs to $(lb)^{0.7}$ body weight is virtually the same, about 25 for rats, goats, and cows. The ratio of milk Cal. to basal metabolism Cal. is also quite constant, 2.1 for rats, 1.9 for goats, 1.7 for cows. The ratios of milk Cal. to $(kg)^{0.70}$, and to $(kg)^{0.73}$ are also quite constant.

The two right-hand columns in this table show, as might be expected, that the ratios of milk energy to estimated basal metabolism, or to $(kg)^{0.7}$ in the "champion" cows, are much above that for the "good" cows, about three-fold in the champion Jersey. The ratio of milk-energy to $(kg)^{0.7}$ is likewise three times as high in the champion Jersey as in the "good" cows.

Incidentally, Gaines' FCM/W dairy-merit index indicates that the champion Jersey is about 70 per cent "better" than the champion Holstein (101:59); the milk Cal/ $(kg)^{0.71}$ index indicates that the champion Jersey is about 33 per cent "better" than the champion Holstein (404:303); by the milk Cal/basal metabolism Cal. method, the champion Jersey is likewise about 33 per cent "better" than the Holstein (5.1:3.7).

According to equation (3) below, a 1700-lb cow producing 138 lbs FCM a day should have the same dairy merit or milk-producing efficiency as a 700-lb cow producing 70 lbs FCM a day. Actually, as shown in Table 22.1, the 1700-lb cow produced only 100 lbs FCM a day. The 1700-lb cow producing 100 lbs FCM a day is thus inferior, from the dairy-merit viewpoint, to the 700-lb cow producing 70 lbs FCM a day.

Summarizing, if the range in live weight of animals is considerable, the relative dairy merit of the animals under comparison is best given by the ratio $FCM/W^{0.7}$ or, perhaps, $FCM/W^{0.73}$, or best, by the dairy merit, that is the percentage TDN converted into milk (Table 22.2). The method of computing these values will be presently explained.

If milk-energy production tends to vary with $W^{0.7}$, how does it happen that Gaines reported that FCM tends to vary more nearly with $W^{1.0}$? A clue to this puzzle is given

⁸ Gaines, W. L., *J. Dairy Sci.*, **23**, 71, 259, 1031 (1940), and references there given. Gaines suggested the use of a special weight, the initial weight, $I. W.$, at the beginning of the lactation period, shortly after freshening.

in Figs. 22.1b and c, which represent the same data on logarithmic and arithmetic grids, respectively.

The slopes of the curves in the two charts (the slopes represent the exponents of W , the value of b in W^b) range from 0.3 for well-fed animals of almost exactly the same age to 1.3 and 2.1 for animals including all ages and all states of nutrition, animals classified by live weight regardless of age and state of nutrition. These differences in slope for the various cow populations thus reflect differences in the composition of the population.

If animals different in age are included in the population classified by weight (regardless of age), the increase in milk production associated with increased body weight is fortified by increase in milk production associated with increasing age during growth.

Fig. 22.1b Milk production as function of body weight on a logarithmic grid. The heavy line represents mature rats, goats, and the 368 "good" cows of all breeds, and has a slope of 0.71 (i.e. $Y = aW^{0.71}$). The other curves represent various groups of cows as shown. Note the wide variations in the slopes of the cattle data due to differences in grouping by ages, nutritional status, and dairy merit.

If animals in different nutritional conditions are included, increase in weight as result of fattening will not increase milk production; on the other hand, if undernourished animals are included, the light animals may have a lower yield than they should and when mixed with well-fed animals will give the curve a greater slope.

Summarizing, unless the cow population is homogeneous with regard to age, state of nutrition, and dairy merit, the slope relating milk yield to body weight is ambiguous. Thus curve 14 (Figs. 22.1b and c) of very high slope represents the same data as curves 2 to 10, each of low slope. Curves 14 and 11 have high slopes because they have animals of different ages, and so on. The differences in slope reflect differences in classification of data.

Instead of employing dairy-merit *indices*, such as $FCM/W^{0.7}$ or $FCM/W^{0.73}$, which are numerically removed from the actual values of *dairy merit*, a table or graph may be constructed giving dairy-merit estimates, estimates of the percentages of consumed *TDN* energy that is converted into milk energy.

Fig. 22.1c. Milk production as function of body weight on an arithmetic grid. The same data as in Fig. 22.1b. The longest heavy line represents the mature rats, goats, and 368 cows ($Y = aW^{0.71}$). The other curves are numbered as in Fig. 22.1b.

Such are Table 22.2 and Fig. 22.2. This table and alignment chart were constructed from the following considerations.

From the preceding chapter, the partition of *TDN* between milk (*FCM*) production and maintenance is given by the relation

$$TDN = 0.305FCM + 0.053W^{0.73} \quad (1)$$

Table 22.2. Estimating Per Cent Efficiency of Milk Production from Body Weight of Cow and Milk Production (4% Milk)

4% milk, pounds per year. (FCM)	Body Weight, Pounds													4% milk, pounds per day

meaning that 0.305 lbs *TDN* is used for producing 1 lb *FCM*, not counting maintenance, and 0.053 lb *TDN* per unit $W^{0.75}$ is used for maintenance.

Now we defined dairy merit by the relation

$$\text{Dairy merit} = 100 \frac{340 \times \text{FCM}}{1814 \times \text{TDN}} \quad (2)$$

The *TDN* is used for two purposes, (1) for producing *FCM* at the rate of 0.305 lb *TDN* for 1 lb *FCM* and (2) for maintenance at the rate of 0.053 lb *TDN* for one unit $W^{0.75}$. Therefore, equation (2) becomes, on substituting the values from equation (1),

$$\begin{aligned} \text{Dairy merit} &= 100 \frac{340\text{FCM}}{1814(0.305\text{FCM} + 0.053W^{0.75})} \\ &= 100 \frac{340\text{FCM}}{553\text{FCM} + 96.1W^{0.75}} \\ &= \frac{61\text{FCM}}{\text{FCM} + 0.173W^{0.75}} \quad (3) \end{aligned}$$

The factor 61, of course, represents the percentage of *TDN* energy converted to *FCM* energy above the maintenance level, not counting the maintenance cost. It means that the *net* energetic efficiency of milk production (not including the maintenance cost) is 61 per cent.

The dairy merit may thus be estimated from equation (3) or more conveniently from Table 22.2 or Fig. 22.2 even though the *TDN* consumption is

not known. The *FCM* production and the body weight are the only data needed.

Fig. 22.2. This alignment chart may be employed for estimating gross efficiency of the milk production process, that is, the dairy merit of the cow. First, the pounds of the given milk are converted to pounds "FCM", that is, to milk containing 4 per cent fat (Table 22.3). The efficiency of milk production is then read from this chart. Thus if it is desired to find the dairy merit, or gross energetic efficiency, of a 700-pound cow producing 8500 pounds yearly or on the average 23.3 pounds daily of FCM (4 per cent milk), place a straight edge between 23.3 on the left (or milk) scale, and 700 on the right (or body-weight) scale, and read the answer 32.5 on the center (or efficiency) scale.

By way of further elucidation of Table 22.2 the following figures indicate how *FCM* production increases with body weight, assuming that the dairy merit is 30 per cent, *i.e.*, that 30 per cent of the consumed *TDN* energy is converted into milk energy. The values are extrapolated low enough to include dogs, rabbits, rats, and so on.

FCM Production in Relation to Body Weight When 30% of TDN Energy Is Converted to Milk Energy

Body weight (lbs)	FCM production (lbs/day)	Body weight (lbs)	FCM production (lbs/day)	Body weight (lbs)	FCM production (lbs/day)	Body weight (lbs)	FCM production (lbs/day)
1800	39.5	1100	27.5	400	13.0	10.0	0.88
1700	38.0	1000	26.0	300	10.5	5.0	0.53
1600	36.0	900	24.0	200	7.8	1.0	0.16
1500	34.0	800	21.0	150	6.4	0.7	0.126
1400	33.0	700	19.6	100	4.7	0.1	0.030
1300	31.5	600	17.5	75	3.8		
1200	29.0	500	15.3	50	2.9		

Summarizing, it is suggested that the dairy value of cattle be estimated not by the absolute amounts of milk production, because this varies with body weight, nor by the ratio of milk production to body weight (unless the range in weight is narrow), because this ratio necessarily declines with increasing body weight, but by the ratio $FCM/W^{0.7}$ or, preferably, by the dairy merit Table 22.2 or Fig. 22.2, defined as the percentage of TDN energy consumed, that is, converted into milk. *Dairy merit* in the animal is identical with *gross energetic efficiency* of the milk production process.

22.4: The influence of dairy merit on profit in animals of equal body weight.

It is evident that, as the production level increases, the maintenance tax—including feed and labor—per unit milk production decreases. The labor per unit milk production decreases because it does not take much more time to milk, clean, feed, and manage a superior than a mediocre cow. In brief, the more milk a cow of a given weight produces, the greater the profit per head, per herd, and per pound of milk produced.

Roughly speaking, the total milk-production cost is double the feed cost for both high- and low-milking cows. This is exemplified by the following values.⁹

Influence of Milk Yield on Cost of Milk Production

Milk fat production (lbs/yr)	150	200	250	300	350	400	450
4%-milk production (lbs/yr)	3750	5000	6250	7500	8900	10000	11250
Estimated feed cost (\$)	52	61	68	74	81	88	94
Estimated total cost (\$)	104	122	136	148	162	176	188
Cost per 100 lbs of 4%-milk	2.77	2.44	2.18	1.97	1.85	1.76	1.67

As the milk yield increases, the feed cost *per unit milk* becomes less, because of the saving in the feed cost of maintenance per unit milk production. The decrease in *feed cost per unit milk* is paralleled by decrease in *labor cost per unit*

⁹ Reported in chart form in the *American Dairymen* (Aug. 5, 1941). The values (except for the 4%-milk row computed by the writer) were read from the chart by permission of Leland W. Lamb, who obtained the feed figures from the Dairy Records office, Cornell University. The body weights are not given and the significance of these values is, therefore, somewhat mixed. The increase in milk production is probably due in part to increased dairy merit, in part to increased weight, and in part to better feeding.

milk because it does not take more time to milk, feed, clean, etc. a superior than an inferior animal. It is concluded that profits per animal and per unit milk increase with increasing milk production in the approximate manner given in the above table.

22.5: The influence of body weight on profit in animals of equal dairy merit. The cost of milk production is usually divided into feed 50 per cent, and over-

Table 22.3. Table for Converting Milk of Given Fat Percentage to "4 Per Cent Milk" by Means of Table 22.1*

Column A gives fat percentages, column B corresponding conversion factors, which when multiplied by pounds of milk produced, will convert the given milk to 4% milk. Thus if a cow produces 10,000 pounds of 3% milk multiply 10,000 by 0.850 and get the answer 8500 pounds of 4% milk. In other words 10,000 pounds of 3% milk contains the same amount of energy as 8500 pounds of 4% milk.

* The conversion factors in this table were computed from Gaines' formula " $FCM = .4M + 15F$ ", where FCM (fat-corrected milk) is gross energy value in terms of normal average cows' milk of 4 per cent fat content, M is actual milk and F is fat, all in the same unit of weight." (W. L. Gaines, Univ. Ill. Agr. Exp. Sta. Bull. 308, 1928.)

head 50 per cent (labor and management 30 per cent, miscellaneous 20 per cent). Since the overhead costs are substantial, it is necessary to discuss the influence of body weight upon them.

If *dairy merit is equal in large and small animals*, the larger the animal the more milk she will produce. Since it does not take more time to milk, feed, clean, and manage a large cow producing more milk than a small cow producing less milk, it is obvious that the labor and management and other

overhead costs should be less for large than for small animals producing a given amount of milk.

By way of illustration, let us assume that it is desired to produce the equivalent of 1000 lbs of 4 per cent-milk (*FCM*) a day at a gross energetic efficiency of 30 per cent. It may be shown from the definition of gross energetic efficiency that 625 lbs *TDN* would be consumed per day to produce 1000 lbs milk (*FCM*) per day, *regardless of the size of animals*. The number of animals of different body weight required to produce the 1000 lbs (*FCM*) per day is given in the following table.

Influence of Body Size on Number of Animals Required to Produce 1000 lbs *FCM*/day at 30 per cent Efficiency

Weight of animal (lbs)	Number of animals required to produce milk at 30% efficiency
1700	26
1400	30
1000	38
900	42
700	53
100	200

Obviously it takes more labor to milk, feed, etc. 200 goats than 53 cows; 53 than 38 cows; 38 than 26 cows. Therefore, *per 1000-lbs* milk yield and when dairy merits are equal, the larger the animals, the fewer required to produce the milk, and the less the overhead costs per unit milk produced.

Using different wording, about twice as much milk (at nearly half the labor cost) may be produced from a *given number* of 1700-lb cows than from 700-lb cows, provided that the dairy merits of the two are equal; and a given number of large animals constitute a larger business with larger profits than small animals of the same dairy merit.

The following example illustrates how a difference in body size of an order frequently found in dairy herds, in animals of the *same dairy merit*, affects the monetary profit.

Assume that each of 2 groups of cow's produces 1000 lbs 4 per cent milk a day, selling at \$2.00 per 100 lbs. The feed cost is the same, \$1.50 per 100 lbs *TDN*; dairy merit of the cows, or the efficiency of milk production, is the same: 30 per cent of the *TDN* is converted into milk. The only difference is that in one group the animals weighed 900 lbs, in the other 1400 lbs. How do the two herds compare from the profit viewpoint?

Solution:

	900-lb cows	1400-lb cows
No. cows needed to produce 1000 lbs. 4%-milk daily at 30% efficiency.....	42	30
<i>TDN</i> needed to produce 1000 lbs. 4%-milk daily at 30% efficiency.....	625 lbs/day	625 lbs/day
Milking time.....	13.6 hrs	10 hrs
Housing, records, taxes, etc.....	42x	30x
	(x = 10¢ per cow per day)	

Cost for 900-lb herd = feed \$9.37
 labor 2.72
 records, etc. 4.20
 16.29

Cost for 1400-lb herd = feed \$9.37
 labor 2.00
 records, etc. 3.00
 14.37

Return from milk = \$20 per day

Profit for the herd of 900-lb cows \$20.00 - \$16.29 = \$3.71 per day

Profit for the herd of 1400-lb cows \$20.00 - \$14.37 = \$5.63 per day

Relative profit = $\frac{5.63}{3.71} = 1.5$ as much for the herd of 1400-lb cows as for the 900-lb cows.^{2a}

The above computations indicate that if dairy merit and price per unit 4 per cent-milk are the same for milk of the small and large cows, the profit on a *given amount of 4 per cent-milk* produced is 50 per cent greater when produced by the 1400-lb than by the 900-lb cows. The profit differences, of course, increase with increasing body-size differences. This type of reasoning is not applicable with the same force to pasture fed cattle where the housing and management items are of a different order.

Fig. 22.3a.

The gross efficiency of milk production tends to decline with increasing body weight.

The above estimates are based on the assumption that dairy merit and other conditions are equal in large and small cows, which may not be the case. Small cows tend to be more efficient than large ones (Fig. 22.3) because the basis for selection has been the production *per cow*. To stay in the herd the small cow has had to produce nearly as much milk as the big cow; but if the small cow produces as much as the big one, she is more efficient because she

^{2a} Since the above was written, a release from Cornell University (reported in *The Surge News*, Aug. 1944) indicates that the "labor income" from milk production on one-fourth of 558 dairy farms with the highest average weight per cow (1140-lb cows producing 7886 lbs of 3.7 per cent milk) was \$944 as contrasted to \$207 "labor income" on one-fourth of the farms with the lowest average weight per cow (792-lb cows producing 5070 lb of 3.7 per cent milk). An increase of 100 lbs in live weight was associated with a 500 to 800 lbs increase in yearly milk yield.

has a smaller body to maintain, and so she expends less of her feed for maintenance.

The fact that large animals are, on the average, less efficient than small ones presents the greater opportunity for raising the efficiency of the large cows, and Table 22.2, or Fig. 22.2, furnishes the necessary (tentative) yardstick for measuring dairy merit of cows, regardless of their body size.

Many practical considerations confuse the size factor. For instance some milks are especially in demand for fluid consumption; others for butter prod-

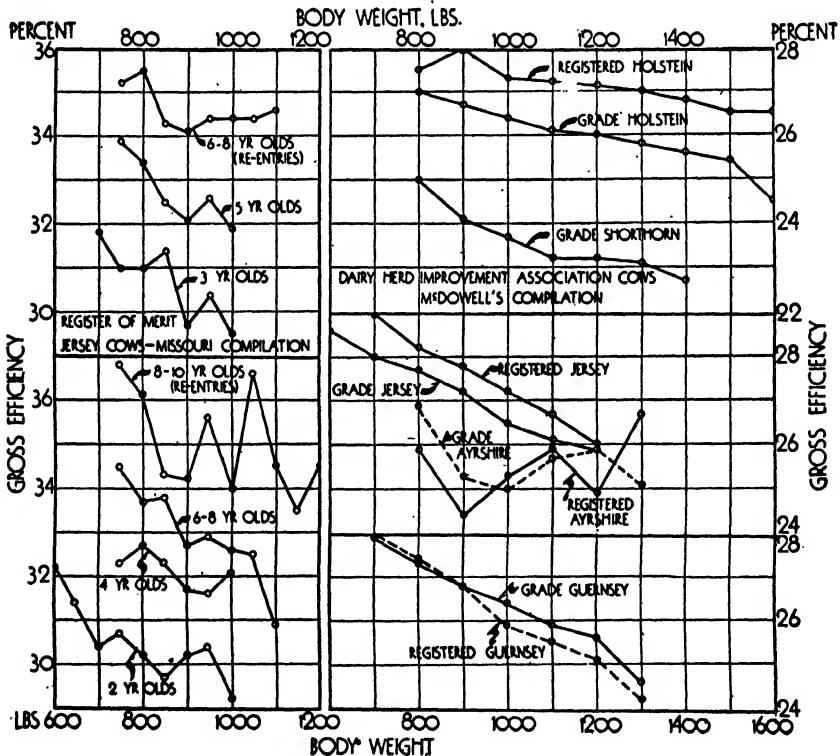

Fig. 22.3b. See legend for Fig. 22.3a.

duction; still others for cheese production. Table 22.4 shows why some milks are preferred for butter and others for cheese—some are relatively richer in fat, others in casein. Color is also a factor.

Topography and climate may favor one or another size of cow. Thus large cows have greater difficulty in grazing on steeply-rolling pastures than small ones, especially on poor pastures which involve much movement. Large animals have a smaller surface area (for dissipating heat) per unit weight than small animals (Ch. 13), and in hot weather large animals may, perhaps, not be able to keep as comfortably cool as small ones (however, the extent of

surface area per unit weight is only one of many factors involved in keeping cool, see Ch. 11).

There are other factors, no doubt, such as the clumsiness of larger cows (Ch. 17) and their greater probability to injury, leg and hoof troubles, and so on, which may counteract the obviously desirable features of large animals. However, when *all conditions are equally favorable for both*, large cows are more profitable for large-scale milk production; in a barn with a given number of stanchions one can produce more milk with large cows than with small ones of the same dairy merit and reduce the production cost per unit milk proportionately.

Fig. 22.4a. The profit of income from milk over cost of feed as function of dairy merit of the cow (gross energetic efficiency of milk production). The two left curves would be much steeper if the other expenses (labor, etc.) were included in the cost, and the curve on the right would bend upwards instead of downwards. Note that profit rises more steeply than energetic efficiency; while profit rises directly with the FCM yield, energetic efficiency increases at decreasing increments. Note also that at 30 per cent efficiency the income from milk is \$70 above the feed cost for the 500-lb. cow; \$130 for the 1000-lb. cow; \$130 for the 1500-lb. cow.

In summary, we should like to modify the phrase used by McDowell¹⁰ "within the breed big dairy cows excell," to "within a dairy-merit class big dairy cows excell." McDowell was only partly right in his conclusion. Large cows may or may not excell within or without the breed, depending on the relative dairy merits of the large and small cows.

22.6. The influence of the plane of nutrition on profit. The plane of nutrition of a given animal is defined by comparison with some feeding standard as reference base, for instance Haecker's feeding standard taken as 100 per cent.

The influence of the plane of gross (feed) energy intake on net (milk energy, meat energy, etc.) energy production was discussed in Chapter 5, as one example of the principle of diminishing increments (Fig. 5.1). This principle was there illustrated

¹⁰ McDowell, J. C., *U. S. Dept. Agr. Circ.*, 114, 1930.

profusely in relation to milk production by tables and charts which may be summarized as follows.

The greater the feed consumption the greater is the milk production, but the *milk production per unit grain or per unit TDN consumption*, or the *percentage of TDN Calories converted into milk Calories* (apparent dairy merit) declines with increasing plane of nutrition.

Since, however, the production per cow is increased, the profit per cow, per stanchion, and therefore for the whole herd tends to increase, as shown by Borland's data (Ch. 5).

Fig. 22.4b. Influence of live weight on profit per cow (top segment), per 1000 pounds body weight (middle segment), and per 1000 pounds milk (FCM) production (bottom segment). The light broken curves indicate the effect when gross energetic efficiency is assumed to be the same, namely, 30.4 per cent for all live weights. The continuous curves represent the observed data. Profit is defined by the difference between monetary return for milk at \$2.00 per 100 pounds FCM and monetary cost of feed at \$1.50 per 100 pounds TDN, ignoring all other expenses. While the profit *per unit milk* is the same in small and large cows, the profit per cow, per stanchion, and therefore for the herd increases very rapidly with increasing live weight, at the same *dairy merit* of 30.4 per cent.

(See also Fig. 22.4a.) The profit per cow in Borland's table refers to that of milk income over feed expenditures (not counting the other 50 per cent of the expenses, for labor, etc.). The profit would increase more rapidly with increasing plane of nutrition if the other expenses were included, especially labor, since the labor cost of feeding, milking, cleaning, etc., is no greater for milking the larger than the smaller amounts of milk.

Profit, of course, also depends on the relative prices of milk and feed (Table 22.5).

The high feeding level may, sometimes, have unfavorable long-range effects, such as development of mastitis, milk fever, and so on. The actual situation is more complex than can be indicated by a table or graph.

Summarizing, average dairy animals produce about 80 per cent as much milk energy on an exclusive, good, roughage ration as they do on such a ration supplemented with about 1 lb grain per 6 lbs milk (*FCM*), as called for by the Haecker Standard. On the other hand, milk production may be increased by about 20 per cent above the level attained by the Haecker Standard by additional grain. The amount of increase depends on the dairy merit of the animal, on her capacity to utilize the extra nutrients (Ch. 5). The increased *TDN* consumption, brought about by increased grain allowance, tends to increase the milk yield at decreasing increments with successive feed units in accordance with the principle of diminishing increments, but often with increasing monetary returns.

22.7: Summary. Each of the three components (1) dairy merit, (2) body size, and (3) plane of nutrition involved in the lactational level, and therefore

in the profit complex, is defined and analyzed while holding the other factors constant. These analyses may be briefly summarized as follows.

(1) *Dairy merit* is defined by the percentage of the consumed *TDN* energy that is converted into milk energy.

The dairy merit of "good" dairy cows is approximately 25 per cent; one-fourth of the consumed *TDN* energy is converted into milk energy. This 25 per cent dairy-merit level pays, approximately, for the dairyman's work, feed, and other expenses at the current rate. "Making money" on cows involves higher dairy merit. What are usually called "superior cows" have a dairy merit of about 33%. The following table indicates in round numbers the milk (*FCM*) production for cows of different weight at dairy-merit levels of 25 and 33 per cent.

Milk Production, lbs *FCM*, for Cows of 25 and 33 per cent Dairy Merit

Body weight (lbs)	25% efficiency		33% efficiency	
	<i>FCM</i> /yr	<i>FCM</i> /day	<i>FCM</i> /yr	<i>FCM</i> /day
600	4700	13	7700	21
700	5100	14	8700	24
800	5800	16	9500	26
900	6200	17	10600	29
1000	6900	19	11600	32
1100	7300	20	12400	34
1200	7700	21	13100	36
1300	8000	22	13800	38
1400	8700	24	14600	40
1500	9100	25	15300	42
1600	9500	26	16000	44
1700	9800	27	16800	46
1800	10200	28	17500	48

Dairy merit is apparently independent of body weight *as such*. Rats, dairy goats, and dairy cattle of all sizes may convert up to about 50 per cent of the ingested *TDN* energy into milk energy. Dairy cattle do not naturally belong to this high-lactation class; they were chosen *by man* because of the size, temperament, and grazing qualities; then by selection developed into high and prolonged milkers.

Small cows, especially within the breed, usually have a higher dairy merit than large ones. This is because of the tendency to evaluate performance by *absolute* milk production rather than by dairy merit, *i.e.*, by the *ratio* of milk produced to feed consumed; so that only such small cows survive in the herd as produce almost as much as the large ones. If a small animal produces as much as a larger one she is more efficient because the small one uses less feed for the maintenance of her smaller body.

It is indicated that the 1700-lb cow that produced the fabulous 1400 lbs butterfat in a year, equivalent to about 42,000 lbs 3.3 per cent-fat milk, has an appreciably lower dairy merit than the 700-lb cow that produced 26,000 lbs *FCM* in a year. Assuming that large cows are biologically capable of developing to the same dairy-merit level as small ones, we shall have 1700-lb cows producing the equivalent of about 50,000 lbs *FCM*, or 2000 lbs butterfat in a year, equivalent in terms of dairy merit to the 26,000 lbs *FCM*, or 1040 lbs butterfat in a year produced by the 700-lb cow.

From the viewpoint of dimensional analysis (Ch. 17), dairy merit may be thought of as the *intensity factor* in the lactational process.

(2) The *capacity factor* in the lactational process is body size—not simple weight, *W*, but *lactationally effective* body size, which appears to be best represented by $W^{0.7}$. This means that increasing body weight 100 per cent increases milk production by only about 70 per cent.

(3) A formula is presented $\left(\text{dairy merit ratio} = \frac{61FCM}{FCM + 0.173W^{0.73}} \right)$ and

a table based thereon, Table 22.2, from which the dairy merit ratio may be estimated if *FCM* and *W* (body weight) are known. It is suggested that this table be employed for estimating dairy merit. If Table 22.2 is sound, a yardstick is made available for measuring lactational ability or dairy merit *independently of body size*. Its usefulness in selecting superior dairy animals may, perhaps, turn out to be comparable in value to that of the Babcock fat test.

(4) It appears that a good roughage, without grain supplement, fed *ad libitum* to "good" dairy cows, yields about 20 per cent less milk than if the roughage is supplemented with about 1 lb grain per 6 lbs milk (*FCM*). Supplementing this Haecker-Standard ration by still more grain increases the milk production to about 20 per cent above the Haecker Standard-fed cows; but the yield increase occurs at decreasing increments in accordance with the principle of diminishing returns (Fig. 5.1). The grain allowance is governed by the quality of the cow, relative costs of feed, labor, and miscellaneous expenses on one hand and the price of milk on the other.

(5) It was shown by a numerical example, involving payment for labor, management, and housing, and when *all other conditions are equal*, that the profit on 1400-lb cows (30 of which are required to produce 1000 lb *FCM* at 30 per cent efficiency) is about 50 per cent greater than on 900-lb cows (42 of which are required to produce 1000 lbs *FCM* at 30 per cent efficiency). Needless to say, "all other conditions" are never equal. There are differences in market demand and in price; in topography and climate; in ability to graze on rolling country and to withstand heat and drought; in clumsiness of larger animals; in greater efficiency of smaller animals as a result, not of body size *as such*, but of the more intensive selection that has been practiced on the smaller animals, and so on, which may nullify, in part, the above generalization concerning the greater profitableness of large animals. This, then, is in the nature of a general rule, and like other general rules has many exceptions. The importance of the exceptions to this general rule will be reduced in proportion to the increase in equitable standardization of milk quality, standardization in feeding, management, and housing conditions, and standardization in selection and breeding on the basis of dairy merit (rather than on the basis of absolute milk yield, which is ambiguous because of its dependence on body size as well as on dairy merit).

Chapter 23

Egg Production: Nutritional and Energetic-Efficiency Aspects

Whereas the nourishment milk is produced for mammals in the breasts, nature does this for birds in the egg. *Aristotle*

23.1: Similarities and differences between egg and milk. Most of the discussion in the preceding two chapters on milk production is applicable to egg production. Poultry, like dairy cattle, convert feed stuffs not suitable for human consumption into food highly prized in the human diet. While the monetary value of eggs produced is, in total, less than that of milk, more farms produce eggs than milk. Egg, like milk, is a secretory product of the reproductive system, and the physicochemical, metabolic, and endocrine mechanisms of egg production are similar to those of milk production.

The reliance of the avian embryo on egg nutriment is more absolute than of the mammalian infant on milk nutriment, because the infant at birth is already in possession of many nutrients stored in the liver and elsewhere. The egg must, therefore, be very perfectly adjusted for supporting rapid avian growth and development.

The closed-in, or cleidoic (Needham), arrangement of the egg imposes certain characteristics on its nutritional properties. Thus, the cleidoic arrangement demands that the egg nutriment be very concentrated; since per unit bulk, fat is more concentrated calorically than sugar, the egg fuel is in the form of fat rather than sugar.

Because every cell has a cholesterol framework, egg is rich in cholesterol, a substance not utilized advantageously in the less rapidly growing, or in adult, humans; and some older individuals may have difficulty in disposing of it.¹

Like milk and meat, egg is an excellent vitamin-mineral-protein supplement to the prevailing high-calorie but vitamin-mineral poor bread-potato-sweets diet. While egg is more expensive per pound or per calorie than milk, it is richer in many supplementary nutrients as indicated in Table 23.1.² Thus per pound as purchased, egg contains twice as much energy, fat, P, and vitamin B₂ (riboflavin); three times as much protein; four times as much vitamin A; eight times as much vitamin B₁ (thiamine); and twelve times as much iron and copper (Tables 23.1b to c).

¹ This is debatable. For a review of cholesterol in the diet, see Brody, S., *Ann. Rev. Biochem.*, **4**, 386-91 (1935).

² Berryman, G. H., and Chatfield, Charlotte, *J. Nut.*, **25**, 27 (1943).

Of course, milk is very much richer in edible calcium and sugar. Market egg contains practically no sugar, whereas milk contains nearly 5 per cent of the uniquely valuable lactose. Egg is very rich in calcium—about 2 gm calcium per egg as contrasted to 1.1 gm per quart milk—but most of it is in the shell. The edible part of the egg contains about one-third as much calcium as milk.

There are many ways of comparing nutritive values of foods, and Table 23.1 compares egg and milk in two other ways—per 100-gm and per 100-Calorie portions. The slight discrepancies between the three tables should not be disturbing considering the biological variability of the material. (All numbered tables are listed at the end of this chapter.)

The proximate composition values are from Chatfield and Adams;³ minerals from Rose and Vahlteich;⁴ vitamins from Daniel and Munsell,⁵ Fixsen and Roscoe,⁶ Sherman and Lanford;⁷ the composition of 100-Calorie portions from Hawley and Maurer-Mast,⁸ slightly modified.

The vitamin concentration of egg is sensitive to that in the feed. Thus⁹ vitamin A was increased five-fold, D ten-fold, B₂ twice in eggs of chickens transferred from indoor to a blue-grass pasture in the sun. Feeding cod-liver oil increased the vitamins A and D in similar manner. The iodine content of egg was increased over 100-fold by dietary method.

The variations in protein and fat of eggs and their responses to the dietary supplies are perhaps of the same order as in milk.¹⁰

Stiebelling¹¹ estimates that about twenty cents of the consumer's dollar is spent for dairy products (which furnish approximately 20 per cent of the Calories in a good diet, 16 per cent of the protein, 62 per cent calcium, 30 per cent vitamin A, 35 per cent vitamin B₂, 5 per cent vitamin C) and about five cents for eggs (which furnish approximately 1.7 per cent of the dietary calories, 4.9 per cent of the protein, 2.7 per cent of the calcium, 6 per cent vitamin A, and 5 per cent vitamin B₂). Milk selling at 14 cents a quart furnishes calories at the same price (two cents per 100 Calories) as eggs selling at approximately 20 cents a dozen.¹² It is, however, unfair to compare milk and eggs on a cost-per-calorie basis, since eggs are not eaten for calories, which are best obtained from bread and potato.

In his encyclopedic "Chemical Embryology," Needham cites extensive data on the variability of eggs in weight and composition. For the present it is sufficient to say

¹² Let 1 qt milk = 700 Cal selling at 14 cents; and 1 doz eggs = 1000 Cal. Therefore a dozen eggs should sell, to give the same price per Calorie, $14 \times \frac{1000}{700} = 20$ cents a dozen.

that the market egg of the domestic fowl weighs about two ounces (55-59 gm), of which about 11 per cent is shell, 30 per cent yolk, 59 per cent white. We found¹³ the fuel value of the 58-gm egg to be of the order of 90 Cal. Computation from Chatfield and Adams' table yields 78 Cal. The average market egg on which Chatfield and Adams' averages are based probably weighs less than 58 gm.

The yolk weighs about 17.4 gm, the white 34.2 gm, the shell 6.4 gm. The protein weighs about 7 gm, the fat 6.7 gm. The white weighs twice as much as the yolk, but the fuel value of the white is only one-fourth that of the yolk, because: (1) the yolk has 51 per cent solids as compared to the 12 per cent solids of white, and (2) the yolk solids are mostly fat (63 per cent fat, 33 per cent protein) as contrasted to white solids, practically all protein. (The watery nature of egg white suggests that its function is similar to that of the jelly of frog eggs: it is principally a water reservoir for the embryo).

The following notes outline the reasons for the longer time taken to produce unit egg energy than unit milk energy.

The germ cell (germinal disk when not fertilized, blastoderm when fertilized) and the surrounding nutrient yolk are wrapped in the vitelline membrane (Fig. 23.1a). The yolk is composed of a series of concentric dark and light layers. The dark yolk is in turn composed of structural units ranging in size from 0.025 to 0.100 mm in diameter, and the light yolk of units up to 0.07 mm.

The albumen is also made up of several layers. Closely adhering to the vitelline membrane is the dense chalaziferous layer connected with the chalazae. This layer is surrounded by the "dense white" layer which comprises 40 to 60 per cent of the total egg white. This layer is a fibrous meshwork filled with thin albumen. Surrounding this fibrous layer is a more liquid mucilagenous albumen layer. The yolk and albumen are packaged in a shell composed mostly of CaCO_3 (93-98 per cent) lined with outer and inner shell membranes.

Fig. 23.1b indicates the time relations in the oviduct as reported by Warren and Scott.¹⁴ The germ and yolk are formed in the ovary; the albumen, shell membranes, and shell in the oviduct.

When the yolk is fully formed, the follicle housing it ruptures, and the germinal disk and yolk system escape into the infundibulum, or funnel, of the oviduct. Fertilization occurs in the infundibulum, and within about half hour of its arrival the egg departs for a journey of about 25 hours, travelling slowly through the magnum (about 3 hours), isthmus (about 1½ hours), uterus (about 20 hours), vagina (about ½ hour). Most of the albumen, including the chalazae, is secreted in a period of about 3 hours in the albumen-secreting portion of the oviduct, and the remaining in the isthmus and uterus sections. The membranes are formed in the isthmus, and the shell in the uterus.

But the time factor in the formation of albumen and shell in the oviduct is only one,

¹³ Virgil Herring analyzed 58-gm eggs in the writer's laboratory with the following results, expressed in Calories:

combustion value of the whole egg including shell.....	92.4
combustion value of egg less shell.....	90.8
combustion value of 1 gm whole, wet egg including shell.....	1.6
combustion value of 1 gm whole dry egg including shell.....	4.987
combustion value of 1 gm dry egg not including shell.....	6.987

It may be noted (Ch. 3) that Murray reported 6.94 Cal per gm dry egg and 5.1 to 6.1 Cal per gm dry chick; Tangl reported 1.69 to 1.73 Cal per gm dry egg. In dietetic practice it is customary to assume that the combustion value of a dozen eggs is 850 Cal, or 71 Cal per egg. Our combustion value of a 58-gm egg, namely, 90.5 Cal or 696 Cal per dozen, weighing 700 gm, is considerably higher than that computed from Chatfield & Adams' (see Table 23.1) combustion constants, namely 78 Cal per egg.

¹⁴ Warren, D. C., and Scott, H. M., "The time factor in egg formation," *Poultry Sci.*, **14**, 195 (1935); *J. Agr. Res.*, **51**, 565 (1935). Conrad, R. M., and Scott, H. M., "Formation of the egg," *Physiol. Rev.*, **18**, 481 (1938).

perhaps a relatively small, part of the total time involved in the formation of an egg. Little is known about the time relation of yolk and germinal disk formation.^{15, 16} The speed of egg production—and consequently its *gross* energetic efficiency—may not be limited by the speed of migration in the oviduct, but by the speed of maturation of the

Fig. 23.1a. Structure of the egg. A, shell; B, outer shell membrane; C, inner shell membrane; D, air cell; E, outer thin portion of albumen; F, middle jelly-like portion of albumen; G, inner dense portion of albumen; H, vitelline membrane; I, chalaza; J, thin film of white yolk inside of vitelline membrane; K, layers of yellow yolk separated by thin layers of white yolk; L, germinal disk; M, central part of yolk filled with white yolk; N, slender tube connecting center of yolk with region of germinal disk. Each of these structures is in turn made up of smaller structures, as for example, the shell is composed of: (a) gelatinous outer coating; (b) outer porous layer; (c) middle granular layer; (d) inner crystalline layer; (e) inner face layer, each of different structure. The inner shell membrane is a fine cellular structure bound by many intertwining fibres; the outershell membrane coarser in structure than the inner, is also composed of fibers, and so on. (After E. W. Benjamin, Cornell Agr. Exp. Sta. Bull., 353, 1934.)

Fig. 23.1b. Time relation of migration of the egg in the domestic fowl.

ova in the ovary. Fig. 23.1c indicates the migration of the egg in the ovary and oviduct as pictured by Mathias Duval in 1889.

Summarizing, egg as nutriment closely resembles milk as nutriment in its evolutionary, nutritional, agricultural, physicochemical, and social-economic

aspects. From the standpoint of contemporary nutritional human needs, egg is richer than milk in iron, copper, vitamins D, A, and B₂, and in fat; egg is poorer than milk in calcium, sugar, nicotinic acid and vitamin C.

From the viewpoint of gross *energetic* efficiency of egg production, it is more expensive energetically to produce unit egg energy than unit milk energy for the following reasons. While the mammal might be said to dump her relatively homogeneous milk nutriment into a cistern tapped at will by the infant, the bird packages her dietary endowment to the young most elaborately (Fig. 23.1a). But it takes *time* to build an elaborate structure (Figs. 23.1b and c); and during this *time*, the builder must be maintained. Hence the *maintenance cost* is greater, and therefore gross efficiency is less for producing unit egg energy than unit milk energy. As previously noted, however, egg is not consumed for its energy content alone.

The relation between profit and energetic efficiency is somewhat similar for egg and milk production. The relation between profit and body size for egg production might be the same physiologically as for milk production; actually, for reasons which will be discussed, it is not.

In view of the similarities between egg and milk production (physico-chemical, physiological, nutritional, social-economic, agricultural) the reader is referred to the detailed discussion on milk production in Chapters 21 and 22.

23.2: Energetic efficiency of egg production.¹⁷ The energetic efficiency of egg production is evaluated by the same method as for milk production described in Section 21.6 with the aid of the following two basic equations:

Gross energetic efficiency of egg production

$$= \frac{\text{egg calories produced}}{\text{feed (TDN) calories consumed including maintenance feed}} \quad (23.1)$$

Net energetic efficiency of egg production

$$= \frac{\text{egg calories produced}}{\text{feed (TDN) calories consumed less TDN expended for maintenance}} \quad (23.2)$$

If body weight and composition are assumed to remain unchanged, the gross efficiency with respect to *TDN* (total digestible nutrients) is computed from the equation

$$\text{Gross energetic efficiency of egg production} = \frac{1.6 \times \text{egg grams produced}}{3 \times \text{feed grams consumed}} \quad (23.1a)$$

¹⁷ Brody, S., Funk, E. M., and Kempster, H. L., Univ. Mo. Agr. Exp. Sta. Res. Bull. 278, 1938. Detailed numerical data are there given.

in which 1.6 and 3 are, respectively, the calorie equivalents per gram of whole egg and of assumed TDN^{18} in the feed.

The *net efficiency* (not including maintenance cost) is estimated by mathematical partitioning of the feed consumed between its three uses: egg production, maintenance, and body-weight gain (or loss). The partition equation for egg production is of the same form as for milk production (Sect. 21.6):

$$\text{Feed} = B(\text{egg}) + CW^{0.73} + D \Delta W \quad (23.3)$$

This is a statement of an energy balance between the TDN (feed) consump-

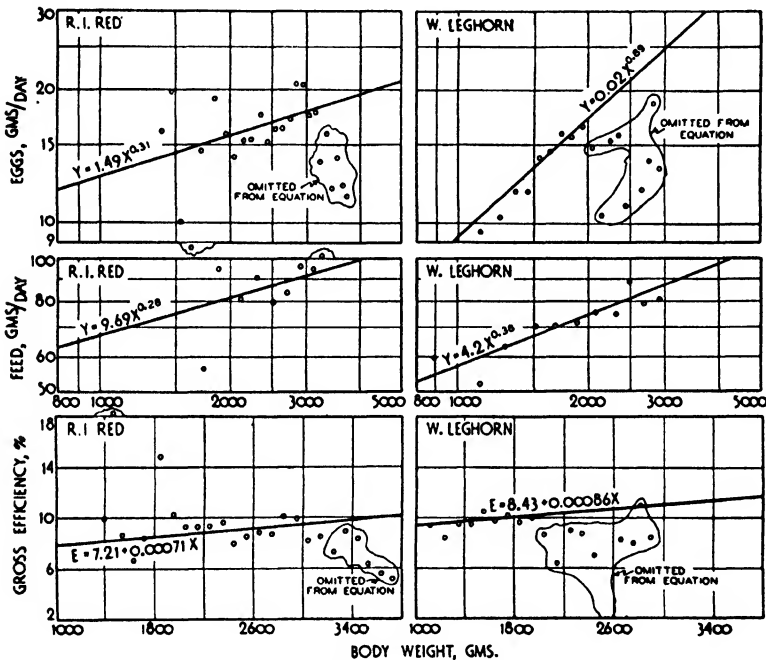

Fig. 23.2. Influence of body weight on egg (grams) production, and on feed consumption during 28-day periods and gross efficiency of egg production of our birds.

tion on the left side, and egg production, maintenance, and weight-gain on the right side.

The significance of its parameters (B , C , D ,) depends on the accuracy of the basic data (TDN , egg, live weight, live-weight gains), the size and homogeneity of population, range of data, and method of fitting equation to data.

We solved the equation by the method of least squares, which determines the

¹⁸ The TDN was estimated from Morrison's tables in his "Feeds and Feeding" without implying, however, that it is appropriate to estimate TDN for chicken feeds from these tables.* The use of TDN values, even if of a makeshift nature, is necessitated by our comparative viewpoint, as for comparing efficiencies of egg and milk production.

values of B , C , and D so that the sum of the squares of the differences between observed TDN and TDN computed from this equation is a minimum. The solution consists, as explained in Section 21.6.5, in substituting in three "normal equations," and simultaneously weighting the trends of TDN with each of the other three variables (egg, W , ΔW) in such manner as to give a minimum value for the sum of the squares of the differences.

The partition equation (23.3) was fitted to 2237 of 28-day periods (Fig. 23.2) with the following results:¹⁷

$$\text{Feed} = 0.692 (\text{egg}) + 0.300W^{0.73} + 1.07 \Delta W \quad (23.4)$$

which indicates that 0.692 gm feed was expended for producing 1 gm whole egg (including shell); 0.30 gm feed was expended to maintain $W^{0.73}$ gm body weight; and 1.1 gm feed was expended for changing body weight by 1 gm. We assumed that the same amount (but of different sign) of feed was involved in gaining or losing unit body weight. This assumption is subject to criticism. Since, however, the fraction of the feed used for body weight changes is relatively insignificant, the assumption was perhaps justified in the interest of simplified computations.

The *net efficiency*, that is, the ratio of egg calories produced to TDN consumed above the maintenance and weight-gain cost, is therefore given by the relation

$$\begin{aligned} \text{Net efficiency of egg production} &= \frac{\text{gm egg produced} \times 1.6}{\text{gm feed consumed for eggs} \times 3} \\ &= \frac{1 \times 1.6}{0.692 \times 3} = 0.77 \text{ or } 77\% \end{aligned}$$

(1.6 is the caloric value of a gram egg; 3 is the caloric equivalent of TDN in a gram feed.)

The above numerical result means that under the given condition, out of 100 Cal. TDN consumed *above maintenance and above live weight changes* as computed by us, 77 Calories were recovered in the eggs, and the remainder expended for the cost of various intermediate transformations. It may be recalled that the *net efficiency* of milk production with respect to TDN in 243 experiment-station cows was computed to be 62 per cent. The difference between 62 and 77 per cent in *net efficiencies* of milk and egg production appears to be within the limits of variability of the data and equation constants.¹⁹

¹⁹ Theoretically equations (23.3) and (23.4) should have an additional parameter constant A , thus:

$$TDN = A + B (\text{egg}) + CW^{0.73} + D \Delta W \quad (23.5)$$

Fitting this equation to the data by the method of least squares resulted in the equation

$$\text{Feed} = 7.77 + 0.688 (\text{egg}) + 0.273 W^{0.73} + 1.09 \Delta W \quad (23.6)$$

the constants of which do not differ substantially from those in equation (23.4). The standard error of estimate of equation (23.4) is 17.70 and of equation (23.6) is 17.71; the index of correlation of equation (23.4) is 0.722, and of equation (23.6) is 0.724, indicating that leaving out the parameter constant does not appreciably alter the situation.

A computation in the following section indicates that the net efficiency of egg production is only 54 per cent.

The *net* energetic efficiency thus appears to be of the same order for egg as for milk production; that is, the energetic efficiency of transforming *TDN* into eggs when maintenance cost is not included is of the same order as the efficiency for milk production when maintenance cost is not included. It is therefore concluded that the *ovary and oviduct produce egg from egg precursors with the same energetic efficiency as the mammary gland produces milk from milk precursors.*

It is emphasized that *gross* efficiency is simply the ratio of energy in eggs produced to energy in *TDN* consumed (assuming 1 gm *TDN* has an energy content of 4 Calories); no assumptions are involved in estimating gross efficiency except that the body weight and body-composition remain unchanged, or are properly corrected for. Net efficiency is, on the contrary, quite involved. The numerical value of net efficiency is dependent not only on the reliability of the basic data (egg energy produced, *TDN* energy consumed, gain or loss in live weight) but also on the number of birds included in the computations, range in live weight and egg production, homogeneity with regard to relative inherited capacities for egg production, fattening, maintenance-need levels, etc.

Instead of expressing net efficiency in the form of percentage energy in the egg produced to the assumed *TDN* energy in the feed consumed above maintenance, it may be expressed in the more familiar terms of feed consumed above maintenance per egg or dozen eggs produced. Thus from equation (23.4):

0.692 gm feed is consumed above maintenance for producing 1 gm egg
or 0.692 lbs " " " " " " " " 1 lb "
since 1 egg weighs about 2 oz, or $\frac{1}{8}$ lb. Therefore

$0.692 \times \frac{1}{8} = 0.0865$ lb feed is consumed above maintenance for producing 1 egg;
or

$0.0865 \times 12 = 1.04$ lb feed is consumed above maintenance for producing a dozen 2-oz eggs.

Since 2 oz is equivalent to about 57 gm,

$0.692 \times 57 = 39.5$ gm feed is consumed above maintenance for producing 1 egg weighing 2 oz or 57 gms.

After our original report¹⁷ was published, our attention was called²⁰ to the fact that, employing a different method, Titus²¹ reported that "the amount of this special feed mixture required over and above the maintenance requirement to produce an egg was estimated as being about 40 grams." It is of course gratifying that a practically identical result (40 as contrasted to our 39.5) was obtained independently on other data by another method.

Notes on the data. The data on feed consumption, egg production, body weight, and body-weight gains analyzed above were secured on a total of 289 birds, 174 White Leghorns and 115 Rhode Island Reds, during the course of three years (1934-7). A total of 2524 28-day observations were made, including 1429 periods on White Leghorns and 1095 periods on Rhode Island Reds. However, some of the periods were incomplete and were omitted, with the result that the following efficiency computations are based on 2237 28-day periods.¹⁷

²⁰ Titus, H. W., "Food and Life", Yearbook of Agriculture, U. S. D. Agriculture, Washington, p. 802, 1939.

²¹ Titus, H. W., "The gross maintenance requirement of White Leghorns," *Poultry Sci.*, 8, 80 (1928-9).

The birds were kept in individual compartments in laying batteries. Each compartment was supplied with a feeding box containing the following all-mash mix:

	lbs. <i>TDN</i> *
Ground corn, 35 pounds.....	29.3
Ground wheat, 20 pounds.....	15.68
Ground oats, 15 pounds.....	10.73
Wheat bran, 10 pounds.....	7.02
Alfalfa leaf meal, 5 pounds.....	2.85
Meat scraps, 8 pounds.....	5.46
Dried butter milk, 5 pounds.....	4.28
Cod liver oil, 1 pound.....	1.14
Salt, 0.05 pound.....	
Finely ground limestone, 2.0, pounds.....	
Total, 101.5 pounds.....	76.47

* Morrison's Conversion Tables.

We assumed that 1 gm *TDN* has an energy value of 4 Calories, or 1 pound *TDN* 1814 Calories. By this assumption 1 gm of this feed mix was computed to be equivalent to 3 Cal *TDN*, or 1360 Cal *TDN* per pound of feed. Future computations in this chapter will be made with reference to feed consumed, equivalent to 3 Cal *TDN* per gm feed or 1360 Cal *TDN* per pound feed.

The energy value of eggs was found by analyzing a dozen No. 1 (58 gm) eggs.¹³ The fuel value of the egg was found to be 1.6 Cal. per gram whole egg including shell.

Our data are unsatisfactory in several respects. The housing was very poor—too hot in the summer, too cold and drafty in the winter—with resulting unsatisfactory health and production of the birds. Of course, the lower the production level the greater the maintenance cost per egg produced, and consequently the lower the gross energetic efficiency; but this may not influence seriously the *net* efficiency. This situation explains in part the unusually low gross efficiency level of egg production of this group of birds, as will be explained presently.

23.3: Influence of live weight on gross efficiency of egg production. The following table (on New Hampshire Red pullets) indicates the method employed for computing gross efficiency of egg production. The complete data are given in the original report.¹⁷

Date of 28-day period	No. of birds in group	Ave. live wt. (gm)	Ave. daily live wt. gain	Eggs per bird per period	Average daily egg production			Ave. daily feed consumption		% energetic efficiency not corrected for weight gains
					gm/day	Cal./day	% possible production	gm/day	<i>TDN</i> (Cal./day)	
10/23/37 to 11/19/37	88	2282	4.8	10.3	20.0	32.0	36.8	112.0	336.0	9.5
11/20/37 to 12/17/37	73	2419	6.9	9.3	18.8	30.1	33.2	114.6	343.8	8.7
12/18/37 to 1/14/38	71	2544	1.6	15.5	33.6	53.8	55.4	129.9	389.7	13.8

This table shows that this particular group of birds produced eggs at a gross energetic efficiency (with respect to the assumed *TDN* energy in the feed) of 9 to 14 per cent, depending on the number of eggs produced during the period. As indicated in Fig. 1.1, the gross energetic efficiency of egg production rises with increasing egg production but at decreasing increments in accordance with the law of diminishing increments, approaching a gross efficiency of 15 to 35 per cent as limit, depending apparently on body weight. It appears that large fowls cannot attain as high an efficiency level as small, for reasons to be discussed presently.

As is generally known, and as is illustrated in Figs. 23.3a and b, egg weight and in some cases egg number tend to increase with increasing body weight up to a certain body-weight level, following which egg number decreases. The body weight of maximum production is of the order of 4 lbs in Leghorns and 5½ lbs in the heavier breeds, as R.I. Reds and B.P. Rocks. Fig. 23.2 shows that the production and gross efficiency levels of our birds increased up to body weight about 3000 gms (about 6 lbs) in the R.I. Reds, and 1800 gms (about 4 lbs) in the Leghorns, and then decline. The slight increase in efficiency with increasing body size up to these body-weight levels appears to be due

Fig. 23.3a. Rise in egg number per year with increasing body weight. For the sources of the Canadian egg-laying contest data see Dominion of Canada, Dept. Agr. Bull., 139, Ottawa.

not to body weight as such, but to improved nutritional and health conditions of the birds.

It is instructive to compare the efficiency of our birds as indicated in the above discussion with those computed from data in the literature. As the published data were secured for purposes other than efficiency computations, they lack certain details which we shall have to assume. In these computations we shall assume that 1 gm whole egg is equivalent to 1.6 Calories, and 1 gm chicken feed 3 Calories *TDN* per gram, or 1360 Calories *TDN* per pound.

We may first cite data by Byerly, Titus and Ellis²³ listed in columns 1 to 4 of the following table, to which we have appended column 5 giving the computed gross energetic efficiency of the egg production. Column 5 indicates that the gross energetic efficiency of egg production of 200-egg fowls is only about 14 per cent. Some of the food, however, was used for growth, for which no correction was made.

We also computed (columns 3, 4, 6, 7 in table 23.2) the gross efficiency of egg production of the birds in seven egg-laying contests in Utah.²⁴

Fig. 23.3b. Canadian-contest data continued.

These results indicate that the overall energetic efficiency of the Utah Leghorns is of the order of 17 per cent on a yearly basis, and 19 per cent for the highest production period (May-June). These 19 per cent efficiency birds may be considered to be fairly high-producing fowl, comparable to the high-producing cows for which we found an overall percentage efficiency of 33 per cent.

Waite²⁵ similarly summarized data for six Maryland egg-laying contests (November 1925-October 1931). We computed the gross efficiency as before. Egg weights were

²³ Byerly, T. C., Titus, H. W., and Ellis, N. R., *J. Agr. Res.*, 46, 1 (1933). "

²⁴ Alder, B., *Utah Agr. Exp. Sta. Bull.* 248, 1934.

²⁵ Waite, R. H., *Maryland Agr. Exp. Sta. Bull.* 359, 1934.

not given. We assumed that the eggs weighed 56 grams each. The results given in Table 23.3 indicate that the gross efficiency of egg production varies, among other factors,

Efficiency of Egg Production Computed from Byerly, Titus and Ellis

Diet No.	Eggs produced per gram of feed eaten after average date of 1st egg	Egg/hen per pullet year	Change in body weight (gm)	Gross energetic efficiency* (not cor- rected for change in body weight)
1	0.229	197.0	316	12.2
2	0.212	187.5	252	11.3
3	0.231	188.1	341	12.3
4	0.205	168.0	358	10.9
5	0.172	145.8	-15	9.2
6	0.219	173.0	296	11.7
7	0.191	159.5	81	10.2
8	0.251	204.5	365	13.4
9	0.198	157.8	—	10.6

* Column 5 was computed on the assumption that 1 gm feed is equivalent to 3 Cal., and 1 gm egg to 1.6 cal. Thus $\frac{0.229 \times 1.6 \times 100}{1 \times 3} = 12.2$ per cent. The data are based on a 344-day period (Sept., 1929 to Aug., 1930).

with the size of the birds. The larger the birds, the smaller, apparently, the gross efficiency.

Summarizing, the yearly gross energetic efficiency of egg production with respect to the assumed *TDN* consumed varies greatly, the maximum of "good" layers being of the order of 19 per cent. It appears that above a certain body-weight level efficiency tends to decrease with increasing size of birds.

23.4: Influence of production level on gross efficiency of egg production. Fig. 1.1 (page 3), based on our data generalized by equation (23.4), represents the functional relation between gross efficiency of egg production and the production level. From this it appears that the maximum efficiency, attained on 300-egg birds, should be of the order of 25 per cent. Does efficiency of egg production actually reach this level? By way of orientation, it is profitable to examine Waite's Maryland egg-laying contest data on egg production and feed consumption of birds classified by production levels. As the egg weights are not given in Waite's report we assumed a constant egg weight of 56 grams. The energetic efficiencies of egg production of three breeds thus estimated are listed in Table 23.3a and b and charted in Fig. 23.4.

Table 23.3b and Fig. 23.4 indicate that "good" layers, good enough to be included in egg-laying contests, have a gross energetic efficiency with respect to *TDN* consumption up to at least 19 per cent. If a *pen* of birds can produce eggs at 19 per cent efficiency, it is probable that *individual* birds may reach a 25 per cent efficiency level. These data therefore substantiate the curves in Fig. 1.1 that the gross efficiency of egg production may rise to 25 per cent. (While the distribution of the data points in Fig. 23.4 is approximately linear,

Fig. 23.4. Efficiency as function of egg production and feed consumption levels of the Maryland data.

Fig. 23.5. Feed cost per dozen eggs (left axis of ordinates and declining curves) and total feed consumption per 100 fowls per day (right axis of ordinates and rising curves) for fowls of different live weight plotted from Table 23.4. The eggs were assumed to weigh 55 gm. each.

the large values of the intercepts indicate that the curves as a whole are parabolic, similar to the curves in Fig. 1.1.)

Summarizing, the energetic efficiency of egg production, like that of milk production, increases with increasing production level in accordance with the law of diminishing increments. The energetic efficiency of pens of birds at the given egg-laying competitions ranged from about 10 to 19 per cent with respect to *TDN* consumed. Assuming that the *net* efficiency (not counting maintenance cost) of egg production is constant (about 1 lb feed per dozen eggs) these 10 per cent differences in gross efficiency are due to differences in maintenance tax imposed on the egg. The larger the number of eggs produced, the smaller the maintenance per egg, and consequently the higher the gross efficiency.

Fig. 23.6. Feed consumption as function of egg production number, based on the Maryland egg-laying competition data.

23.5: Feeding standard for poultry. From equation 23.4, the feed required for egg production is given by the equation

$$F = 0.692e \quad (23.4a)$$

and the feed required for maintenance by

$$F = 0.30W^{.73} \quad (23.4b)$$

in which F , e , and W are respectively feed, egg, and live weight in grams.

The maintenance feeding standard for chickens, computed from equation (23.4a) is given in Table 23.4 (appendix); the amount of feed required for producing egg above maintenance (about 1 lb feed for a dozen 2-oz eggs) was previously computed (Sect. 23.2). The two may be combined into one feeding standard including both feed for maintenance and production, as given in Tables 23.4 and Fig. 23.5.

The following alternate method comes to mind for estimating the feed cost of maintenance and production for the *average-weight* bird. The method is indicated in Fig. 23.6. Plot feed consumption against egg production. The resulting curve should not, theoretically, be linear (the feed consumption should, according to the law of diminishing increments, rise more rapidly than egg production) but it appears to be roughly linear; therefore fit a linear equation to the data. Consider, by way of example, the curve of the Leghorn data: its equations (in various units) show that the feed cost of *maintenance* (not counting egg production cost) of the average bird is 55.7 lbs a year (or 25.3 kg, or 76,000 Cal); that the feed cost for producing an egg (not counting maintenance) is 0.122 lbs (or 55.58, or 166 Cal). The maintenance value, 55.7 lbs feed per year, agrees with

Fig. 23.7. Relation between profit and efficiency. The curves are based on the assumption that 56-gram eggs are sold at 25¢ a dozen and feed (containing 1360 Cal. TDN per pound) cost \$2.00 per 100 lbs., and that there was no other expense or income. Actually, about 10 per cent of the income comes from sale of birds; and the expense for feed is perhaps only 50 per cent of the total expense which includes labor (20-25 per cent), replacement (10-20 per cent), depreciation (8-10 per cent), interest (4-5 per cent), taxes ($\frac{1}{2}$ per cent), etc. Note from this chart that according to these assumptions, it requires a 7 per cent efficiency to cover feed cost, and that the profit increases more rapidly than the efficiency.

the values in the feeding standard for chickens (Table 23.4) assuming that the average Leghorn chicken weighs somewhat below 4 lbs. The production value, 0.122 lbs, or 166 Cal, feed per egg is not unreasonable, because it yields a net efficiency of egg production (for a 56-gram egg) of $\frac{56 \times 1.6}{166} = 54$ per cent. This net efficiency value²⁷ is

lower than the average obtained on our own data (77 per cent), but it is identical with the average net efficiency of milk production of 368 cows (Ch. 21), and the range in net efficiency for milk production in several groups of cows is no less than for egg production of several groups of chickens. Fig. 23.6 is, at any rate, informative, indicating

²⁷ This net efficiency value was confirmed by S. Bird and J. W. Sinclair, *Scientific Agr.*, 19, 542 (1939), who reported 62% net efficiency.

at a glance the relation between feed consumption per year and egg production of several breeds of chickens. It is particularly instructive to note that for a given number of eggs produced the small birds consumed less feed than the large ones. Thus the 200-egg Leghorns consumed nearly 20 per cent less feed than the 200-egg R.I. Reds, while the R.I. Red egg is less than 5 per cent larger than the Leghorn egg. Hence the energetic

Fig. 23.8a. The relation between weight of egg and weight of fowl within the species. The equation indicates that a 100 per cent increase in body weight is associated with a 13 per cent to 19 per cent differential increase in egg weight. Note from Figs. 23.9 and 15.6 that for mature birds of *different species*, the egg weight increases not by 13 per cent to 19 per cent but by 60 per cent to 70 per cent, at the same rate as the maintenance cost increases.

efficiency of egg production is greater for Leghorns than R.I. if both produce the same number of eggs per year.

23.6: Interrelation between profit, gross efficiency of egg production, body size, and egg size. Fig. 23.7 indicates the relation of profit to gross efficiency

of egg production; a relation similar to that for milk production (Fig. 22.4a).

The biologic unit of egg production is, of course, not the pound or calorie of egg, but the individual egg. Consequently, one would not expect an in-

Fig. 23.8b. Since the weight per egg does not increase as rapidly as the maintenance cost with increasing body size, the gross efficiency of egg production must decline (if egg number is the same). This chart shows that, following a certain optimum body weight, the gross efficiency indeed declines with increasing body weight at the differential rate of 6 per cent (W. Leghorn) to 18 per cent (R. I. Red) per pound increase in body weight.

crease in egg number but in egg size with increasing body size; and, as demonstrated in Fig. 15.6, egg size of mature birds of different species increases, on the average, with the 0.73 power of body weight, as does basal metabolism, and probably maintenance cost. Within the species, however, for chickens of different body weight egg size increases not with the 0.73 but with the 0.15

power of body size. It follows from this 0.15 power rise in egg size, that if maintenance cost of chickens increases with the 0.73 power of body weight, and egg number remains constant, the energetic efficiency of egg production decreases with increasing body size.

This situation is similar to the one we met in the tendency for the gross efficiency of milk production to decline with increasing live weight (Sect. 21.6.4) and for a similar reason: the tendency to select in breeding such small birds as produce relatively large eggs. The difference in egg size from small and large fowl is not sufficient to pay for the differences in cost of maintaining small and large fowl, especially if the small fowl is a Leghorn and the large fowl is, for example, a Barred Plymouth Rock belonging to the strain represented in Fig. 23.8a (which shows that the egg weight from a 7-lb Barred Plymouth Rock is the same as that from a 4½ lb Leghorn).

Fig. 23.9. While Fig. 23.8a shows that in the *same species* and breed the egg production rises only 13 per cent to 19 per cent for an increase in body weight of 100 per cent, this chart shows that for closely related but different species—quail, fowl, turkey—the egg size increases 58 per cent for an increase in body weight of 100 per cent.

23.7: Summary. Eggs resemble milk in most respects (evolution as food for young, composition, nutritional value, physicochemical and endocrine mechanisms), and differ in few, especially in concentration of carbohydrate, fat, calcium, iron, copper, and vitamin C.

The *gross* energetic efficiency of egg production is below that for milk production, because of differences in time relations of the two processes, but the *net* efficiency, not involving the time element, is of the same order for milk and egg production, indicating similar efficiency of mammary gland and ovary oviduct systems as energetic transformers.

The feed cost above maintenance for producing average (2-oz) eggs, is of the order of 1 lb feed for a dozen eggs, or 40 gms feed per egg. The maintenance cost of 100 birds per day is: for 2-lb birds, 9.5 lbs feed; for 3-lb birds, 12.8 lbs feed; for 4-lb birds, 15.8 lbs feed; for 5-lb birds, 18.6 lbs feed; for 6-lb

birds, 21.3 lbs feed; for 7-lb birds, 23.8 lbs feed, and so on as given in Table 23.5. A feeding standard is presented for birds of different weights producing at different levels. No alignment charts are given for profit on egg production production as were given for milk production (Univ. Missouri Agr. Exp. Sta., Res. Bull. 239), because such charts were published by Card²⁸ and Byerly.²⁹

Chapter 24

Energetic Efficiency of Muscular Work and Indices of Work-Reserve Capacity

The horse raises what the farmer eats, and eats what the farmer raises. But you can't plow in the ground and get gasoline. You don't have to pay a finance company 10 or 15 per cent to own a horse. Brood mares work on the farm and raise colts as well. *Will Rogers*

24.1: Introduction. Agriculture has tended to follow the lead of industry in ever greater reliance on the free energy (Ch. 2) of petroleum and coal. The horse population has been declining,¹ the tractor population rising. There are several reasons for this trend in addition to the rapid progress in machine design. One is competitive overproduction of petroleum.

Petroleum fuels in most of Europe are too expensive for agricultural use, and America, too, is passing, or soon will be, from an economy of petroleum abundance to one of scarcity, perhaps reversing the present power trend in agriculture, in spite of the current hopes² for developing inexpensive petroleum-fuel substitutes.

Some countries, notably Germany, aware of the dwindling fuel oil, undertook to compensate in part by what is known in Europe as "work rationalization"³ and in this country as "scientific management"⁴ and "efficiency engineering." Systematic investigations have been organized on the physiology of work, especially in Germany. The Kaiser-Wilhelm Work Institute in Dortmund⁵ (Fig. 24.22) was organized with this philosophy in mind. This

¹ There are in the United States about 12 million working horses and mules and about 2 million colts. This is less than $\frac{1}{4}$ of the horse and mule population of 1920. The work-animal power is being replaced by petroleum-power machinery for which about a billion dollars was spent in 1937. While the replacement of horses by machines is rapid on the larger farms, yet perhaps $\frac{1}{2}$ of the U. S. farms—naturally, the smaller units—are operated by horse and mule power.

² There is no precedent for this hope, since with the exception of the relatively negligible hydroelectric developments, our dazzling material progress and discoveries have been based not on developments of renewable energy, but on exploitation of non-renewable "free energy" stored through the past ages. The use of alcohol, vegetable oils, peat and coal derivatives as fuels will be even more expensive in the future than they are at present. For other possibilities, see Ch. 25.

institute is concerned with the physiology of work of man. An institute for the physiology of work of farm animals and farm laborers was being organized (at the time of the writer's visit to Germany in 1931) in Pommritz, near Breslau.⁶ In Budapest, Farkas⁷ and associates were investigating the physiology of work of farm laborers. Russia was organizing a number of work institutes,⁸ as was Czechoslovakia.⁹ While the energetics of work has been investigated in France since the time of Lavoisier, it was only by 1930, apparently following Germany's example, that a special work institute was organized in Paris.¹⁰ An "Industrial Fatigue Board" has been organized in London.¹¹

The interesting aspect of the "scientific management" or "efficiency engineering" movement, which originated in the United States, is that its physiologic aspects have been developed mostly in Europe. With the exception of the Harvard Fatigue Laboratory,¹² there is no institution in this country expressly devoted to the physiology and long-range efficiency of muscular work, certainly not of farm animals. It would seem that some provision should be made for research in this practically important and scientifically fascinating virgin field. Horses and mules are economical to the farmer in monetary cost and to the nation in "free energy" cost; they are especially desirable when ready cash is scarce and feed suitable for horses is plentiful, as is the case during our periodic depressions.

While it is theoretically easy to double or triple the average productive level of dairy cattle by merely utilizing available knowledge (Ch. 22), this cannot be said for improving the work capacity of horses because of lack of comparable knowledge for muscular work. We have learned to measure

precisely milk production capacity but not work production capacity,¹³ and we cannot improve a characteristic by breeding if we cannot measure it.

There is an obvious need for developing methods and their use for measuring quantitatively and precisely actual work performance and potential work capacity, and the influence of environmental and hereditary factors, including age, body size, sex, nutrition, climate, and so on. It is particularly desirable to develop potential work-aptitude tests in the animals when they are still young, analogous to the intelligence and other aptitude tests and quotients employed on children.

The following sections describe some contributions we have made¹⁴ toward measuring work performance and capacity and their relation to the available knowledge in the literature.

Broadly speaking, muscular work may be divided into (1) thermodynamic and (2) physiologic aspects. The thermodynamic aspect is concerned mostly with energetic efficiency, previously discussed in outline (Chs. 1, 2, and 3) and here discussed in detail. Some physiologic aspects were likewise previously discussed, especially anaerobic oxidative metabolism in muscular work (Ch. 6), hormonal (Ch. 7), nutritional (Ch. 20), and temperature and humidity aspects (Ch. 11); oxygen transport as index of work capacity is here discussed for the first time.

24.2: Work performance and its energetic efficiency. *Work performed*, formally defined by the product of weight, *W*, by the distance pulled was measured with a treadmill actuated by a 5-horse power motor (Figs. 24.1, 24.2, 24.21). The rate of *energy expended* was measured by the rate of oxygen consumed.¹⁵ In addition to the treadmill-closed-circuit metabolism apparatus illustrated in Fig. 24.21 used indoors, we also employ an ergometer-open-circuit apparatus used outdoors as illustrated in Fig. 24.23. This field apparatus consists of a weight ergometer modified after the Collins and Caine²² ergometer, and an open-circuit apparatus for measuring and aliquoting the exhaled air, similar in principle to an earlier laboratory apparatus (see page 336). Fig. 24.23 shows how the ergometer is mounted on a trailer pulled by a motor car which also carries the open-circuit metabolism apparatus. The animal pulls a de-

¹³ Laughlin, H. H., *Sci. Monthly*, **38**, 210 (1934): "We have not learned to measure the physiological entity called racing capacity in horses." This is still more true as regards work capacity.

Bull., 367, 1943.

¹⁵ For details, see Chapter 12, where it is explained that the thermal value of oxygen ranges from 4.7 to 5.1 Cal per liter, but that it is convenient to assume that it is 4.825 Cal per liter.

sired weight in the ergometer at the pace set by the car, just as on the treadmill (Figs. 24.1 and 24.21) the animal pulls desired weights at the pace set by the treadmill apron actuated by an electric motor.

The *unit of work* is the kilogram-meter; or the foot-pound, which is the work done by a force of 1 pound acting through a distance of 1 foot. Thus if a force of 1 pound is required to raise a window 1 foot, 1 foot-pound work is done in raising the window. A horse pulling on 150 pounds (as in Fig. 24.1) 2.5 miles (that is 13200 feet) accomplishes

Fig. 24.1. Measuring work efficiency. Work consisted in pulling weight, W, on a moving horizontal platform actuated by an electric motor at desired speeds; energy cost was computed from the rate of oxygen consumption from tank O_2 .

$150 \times 13200 = 1,980,000$ foot-pounds, or 642 Calories of work. One ft-lb = 0.1382 Kg-meters = 0.005 ft-ton = 0.000324 Cal; or 1 Kg-m = 7.233 ft-lb = 0.002344 Cal; or 1 Cal = 426.4 Kg-m = 3087 ft-lb. (See Sect. 2.4 for other energetic equivalent values.)

Efficiency is the ratio of the Calorie equivalent of work energy performed to Calories expended. Thus a horse pulling 150 pounds (as in Fig. 24.1) 2.5 miles (that is 13,200 feet), accomplishes $150 \times 13200 = 1,980,000$ foot-pounds, equivalent to 640 Calories. If the horse consumed oxygen equivalent to 3210 Calories for performing this work, the energetic efficiency of the work is $642/3210 \times 100 = 20$ per cent.

Fig. 24.2. Photograph of 1500-lb. 4-year Percheron gelding 19 and of 3-year old 600-lb. Shetland Pony 2 which furnished the bulk of the data.

Work rate (work per unit time) is measured in watts, kilowatts, or most commonly in this country in horse power. A horse power is work done at the rate of 1,980,000 foot-pounds per hour, or 33,000 foot-pounds per minute, or 4562.4 kg-meters per minute; or at the rate of 642 Calories per hour or 10.7 Calories per minute. A horse power is equivalent to approximately $\frac{3}{4}$ kilowatt or 746 watts, and a kilowatt is equivalent to approximately $1\frac{1}{4}$ horse power.

Work rate combines three factors into one: load, distance, time; or speed and load. For instance, a work rate of one horse power or 33,000 foot-pounds per minute is obtained when the animal pulls in 1 minute 1 pound for 33,000 feet, or 33,000 pounds for 1 foot. The product is, in both examples, 33,000.

As previously explained (eqs. in Ch. 3) we adopted three energetic efficiency categories: *gross*, *net*, and *absolute*, as defined by the equations:

$$\text{Gross efficiency} = \frac{\text{work accomplished}}{\text{energy expended}} \quad (3.1)$$

$$\text{Net efficiency} = \frac{\text{work accomplished}}{\text{energy expended above that at rest}} \quad (3.2)$$

$$\text{Absolute efficiency} = \frac{\text{work accomplished}}{\text{energy expended above that of walking without the load}} \quad (3.3)$$

The energy expended (denominator) is in all cases measured by the rate of oxygen consumption, that is, by the rate of oxidation of the metabolites. The energetic efficiency of muscular work here discussed thus has a different significance than the energetic efficiency of milk production or egg production discussed in the preceding chapters. In the preceding chapters the efficiency is with reference to the nutrients (TDN) consumed by the animal; in this chapter it is with reference to the metabolites oxidized in the body as measured by the rate of oxygen consumption (Ch. 12). The energetic efficiency with reference to the oxidized metabolites is, of course, greater than it would be with reference to the energy of the consumed feed, because there is considerable waste in converting feed into body metabolites, and this waste, charged to the animal, would reduce the overall computed efficiency.

It is instructive to compare the energetic efficiency of various transformers. The following energetic-efficiency values are from Hill:¹⁶

Steam engines without condensers.....	74%
Steam engines with condensers.....	9 to 19%
Gas engines.....	14 to 18%
Diesel engines.....	29 to 35%

Needham¹⁷ quotes the following figures:

Locomotive steam engine, not over.....	15%
Gas engine with suction producer.....	25%
Diesel engine, best recorded efficiency with high maximum pressure.....	40%
"Electric accumulator".....	70 to 74%

The overall or gross energetic efficiency of farm tractors used in the Middle West (United States) is for the ignition-type¹⁸ about 19 per cent at the belt, or 13 per cent at the draw-bar;¹⁹ for Diesel type,¹⁸ 26 per cent at the belt or 22 per cent at the draw-bar.

As explained before (eq. 2.5) the energetic efficiency of a slow-charging or discharging cadmium standard cell (an isothermal, or constant-temperature, process) is nearly 100 per cent; but the maximum energetic efficiency of the heat engine (which operates by virtue of temperature gradient) is, at the usual temperature, about 50 per cent for the theoretical Carnot engine and very much below this for actual engines as quoted above from Hill and Needham.

¹⁶ Hill, A. V., "Muscular movements in man."

¹⁷ Needham, J., "Chemical embryology."

¹⁸ The ignition type engine has an electrical ignition system and burns refined fuels, such as gasoline; the Diesel type engine does not have an ignition system, the heat of compression ignites the fuel of a lower grade, such as fuel oil.

¹⁹ In the "belt test," the tractor serves as a stationary engine supplying power to rotating machinery through the power take-off and a belt drive. In the "draw-bar" test the tractor pulls a known load, as measured by the draw-bar pull and the speed. The draw-bar efficiency is naturally lower because the tractor expends energy pulling itself over the ground.

Animals are, of course, not heat engines (Chs. 2 and 3) but isothermal converters, yet their maximal energetic efficiency is close to that of heat engines, about 25 per cent for gross efficiency (eq. 3.1), 20 per cent for net efficiency (eq. 3.2) and 35 per cent for absolute efficiency (eq. 3.3). The efficiency of the modern Diesel engine is about 40 per cent.

As before explained (Ch. 3), just as the theoretically (thermodynamically, Ch. 2) maximal efficiency of the Carnot engine is only about 50 per cent, so, according to Hill,²⁰ the theoretically maximum efficiency of a contracting muscle (an isolated frog-muscle strip) is approximately 40 per cent. Hill's theoretic efficiency is analogous to our absolute efficiency (eq. 3.3).

Assuming a theoretic 40 per cent efficiency of muscular work, what becomes of the remaining 60 per cent of the energy? Some is expended for overcoming external resistance (wind, contact of feet with ground, etc.); some is expended for useless incidental motions associated with work, and so on. Most of the energy is, however, expended for overcoming the internal resistance, the

Fig. 24.3. Rise and decline of the net efficiency (not including maintenance, eq. 3.2) of climbing 78 steps with increasing climbing speed. From data by H. Lupton, *J. Physiol.*, 57, 337 (1923).

resistance of the body colloids. This internal resistance is energetically wasteful but biologically useful because without it the animal would "tear his tendons, break his bones, 'pull' his muscles, strain his joints".²⁰

A distinguishing characteristic of animals is that they expend energy even when not performing external work because the internal work—the maintenance cost—goes on regardless of external activity. Hence the all-day energetic efficiency of animals varies with the number of hours worked (Fig. 24.10a to 24.10c).

Then, too, the slower the speed of work, the longer the time taken for holding the muscles in a state of unproductive tension, that is, the greater the maintenance cost per unit work. On the other hand, the greater the speed of work the greater the energy cost in overcoming internal resistance to the muscular contractions of the viscous colloids which make up the body. The

²⁰ Hill¹⁶ and Ch. 3.

efficiency of muscular work as function of speed may, therefore, be expected to be of a rising and declining type²¹ (Fig. 24.3), resembling the rising and declining course of efficiency as function of speed in the automobile (Fig. 24.4).

We have not observed such a rising and declining curve for farm work horses pulling loads at speeds ranging from 1.15 to 3.1 miles per hour as graphed in Fig. 24.5a and b. The highest walking speed was too low to bring

Fig. 24.4. Influence of speed of driving a car on efficiency in terms of miles travelled per gallon gasoline.

Fig. 24.5a. Influence of 3 working speeds on gross work efficiency of horse 19 pulling 300 lbs.

²¹ Efficiency of climbing 78 steps. Plotted from data by Lupton, H., *J. Physiol.*, 57, 337 (1923). Benedict and Murschhouser, H., Carnegie Inst. Publ., 231, 1915, likewise found an optimum speed for walking as shown by the following table:

Meters walked per minute	53	60	80	90	102	140	146
Calories expended per min	64	58	52	51	53	73	77

See also Benedict and Parmenter, *Am. J. Physiol.*, 84, 675 (1928), and Benedict and Cathcart, Carnegie Inst. Wash. Publ., 187, 1913.

out the declining phase of the curve. Attempts to increase the rate of walking beyond 3.1 m.p.h. for 1500-lb horse 19, or 2.2 m.p.h. for 700-lb pony 2, changed the walking into trotting, which we wished to avoid, partly because under working conditions loads are pulled by walking rather than trotting, and partly because of the danger to horse and treadmill in case of breakdown.

The highest rate of work at the walking speed of horses may be too low to bring out the efficiency-depressing effect of the internal friction observed at higher speeds of movement. In such case it would appear that the higher the rate of work the higher would be the *immediate* energetic efficiency of work (Fig. 24.5a). The maximum *long-range* or life-time efficiency, however,

Fig. 24.5b. Influence of pulling speed for given loads, and of load for given speeds on gross efficiency. Gross energetic efficiency rises with increasing speed and load (between the given limits), but the rises are at decreasing increments.

involves liberal rest periods and moderate work rate. One of the problems of "scientific management" or "work rationalization," whether it be of man, cow, or horse, is to determine for animals of given productive capacity the work level for maximal long-range efficiency.

Machines are not usually run at more than 50 per cent of their capacity, and a similar safety margin should perhaps be allowed to man and animals so as to avoid injury or untimely death. The problem in work rationalization is to determine the maximum rate of work that can be carried on day in and day out and still retain vigor to an advanced age. A tentative recommendation for the average horse in Missouri is a tractive draft equal to 10 per cent of body weight pulled at about $2\frac{1}{2}$ miles an hour.²² This will usually amount

²² Collins, E. V., and Caine, A. B., Iowa A. E. Sta. Bull., 240, 1926, reported that it is possible for horses weighing 1500 to 1900 lbs. to work continuously (10 hrs. a day) at a rate of 1 horse power; or that it is possible to exert a tractive effort of 1/10 of their body weights and travel a total of 20 miles per day without damaging fatigue.

to work at the rate of about 4 kilowatts or 1 horse power (33,000 foot-pounds or 10.7 Cal per minute).

Fig. 24.6a shows that while horses can pull loads at least up to 35 per cent of body weight, increases in efficiency become negligible after the draft exceeds

Fig. 24.6a. Gross or overall efficiency and oxygen consumption plotted against horse-power. The oxygen consumption or energy expense increases directly (linearly) with increasing rate of work; the efficiency, however, increases at decreasing increments (exponentially) with increasing rate of work. For a given horse power the oxygen consumption per unit time decreases, and overall efficiency increases with decreasing speed.

15 per cent of body weight: the rise in energetic efficiency with increasing work rate follows the law of diminishing returns (Ch. 1). When horse 19 works at $\frac{1}{2}$ horse power, his efficiency is $12\frac{1}{2}$ per cent; doubling the work rate to 1 horse

power does not double his efficiency to $12\frac{1}{2} \times 2$, or 25 per cent, but only to 18 per cent; at 2 horse-power, his efficiency is not $12\frac{1}{2} \times 4$, or 50 per cent, but only 22 per cent; at 3 horse power his efficiency is not $12\frac{1}{2} \times 6$ or 75 per cent, but only 24 per cent. In other words, the efficiency lags increasingly behind the increase in work rate. Hence the work rate should not increase beyond the point at which the curve begins to flatten decidedly, beyond about 1 horse power, which is the customary rate of work for the 1600-lb horse.

Within the speed limits investigated—that is, 1.1, 2.2, and 3.1 miles per hour—the slower the speed (with a compensatingly higher load) for a given horse power the greater the energetic efficiency of the work. Thus at a working rate of 1 horse power, the efficiencies for horse 19 were: 17 per cent for 3.1 miles per hour; 19 per cent for 2.2 m.p.h.; 21 per cent for 1.15 m.p.h.

Fig. 24.6b. The curves in the lower half of Fig. 24.6a coincide if plotted against the ratio of H. P. to body weight.

Hence from the standpoint of highest energetic efficiency, work horses are more efficient *working at a given horse power* at a slow speed pulling a heavy load than at a high speed pulling a light load, perhaps because the energy losses of overcoming the colloidal resistance of the muscles increase more rapidly than the speed of walking. However, the total energy cost for accomplishing a given job is less at a higher speed because of the saving of maintenance expense resulting from the reduction in the time required to complete the job (provided that the increased time required for recuperation following work at a higher speed is not included in the expense).

Fig. 24.6b shows that if overall or gross efficiency of muscular work is plotted against the ratio of the rate of work (horse power) to body weight, the data for all animals and speeds fall on the same exponential curve

$$E = A - Be^{-kR}$$

in which E is gross energetic efficiency at the ratio, R , of horse power to body weight. The increase in efficiency occurs at diminishing increments, exponentially (Chs. 5 and 16).

If, however, the gross efficiency is plotted against horse power (rather than against the ratio of horse power to body weight) each speed and each animal yields an exponential working curve different from the other curves.

While the graph of *efficiency* as function of work rate is exponential, that of absolute *energy expense* against work rate is linear.²³ The equations, given on the charts,²³ show that the limiting or maximal gross energetic efficiency of muscular work in horses is 25 per cent, and that this maximum is approached

Fig. 24.7. The rate of energy expenditure (Calories, left axis, and pounds T.D.N., right axis) increases directly (linearly) with increasing speed, draft, and horse-power.

exponentially. At the upper limit of our work schedule our larger horses (1500–1600 lb) are seen to have consumed oxygen at the rate of 30 liters a minute, equivalent to an energy expenditure of 150 Calories a minute, which, as will be presently shown by Dill's result, is six times the maximal oxygen consumption in 150-lb man.

Fig. 24.7 shows the influence of speed, draft (load), and horse power on the rate of energy expenditure. At the upper limit of our work schedule our

²³ For detailed mathematical properties of these curves see Univ. Mo. Agr. Exp. Sta. Res. Bull., 244.

largest horse expended energy at the rate of about 9000 Cal/hr, equivalent to about 5 lb TDN/hr.

In computing the three categories of efficiency, gross, net, and absolute (eq. 3.1 to 3.3), it was necessary to measure the energy costs of standing and of walking.

The energy cost of standing above lying is about 9 per cent in man,²⁴ cattle and sheep.²⁵ One unusually heavy steer had a 13 per cent heat increment of standing above lying.²⁵ The ventilation rate was increased by the same percentage but the pulse rate²⁵ increased only 3 per cent. Horses are unique

Fig. 24.8a. The percentage increase of walking over standing metabolism as function of speed. The light circles represent Smith's data on humans to which we have fitted (by method of least squares) the equation. The other data are original.

in not having a heat increment of standing; they do not spend more energy during standing at maturity²⁶ or during growth.²⁷ This is because horses have unusually powerful suspensory and check ligaments, and horses appear to rest and indeed sleep as comfortably while standing as while lying.

Walking consists in successive lifting of the body and the energy cost of walking should vary with the weight of the animal and the speed of walking.

²⁷ Brody, S., and Kibler, H. H., *Univ. Mo. Agr. Exp. Sta. Res. Bull.*, **368**, 1943.

We investigated²⁸ 7 horses ranging in weight from 200 to 1500 lb (91 to 688 Kg); 7 cattle, 850 to 2000 lb (383 to 930 Kg); and 2 men, 70 to 75 Kg with results graphed in Fig. 24.8a. For purposes of comparison we also graphed Smith's data²⁹ on walking in man. Fig. 24.8a shows that *in man* the *percentage* increase in heat production during walking over standing varies

Fig. 24.8b. Lower quadrant: *net* energy expense of walking (energy cost of walking, not including the energy cost of standing); upper quadrant: *overall* energy expense of walking (including the cost of standing). Values are in terms of Calories per unit live weight and unit distance walked (metric units on top and right; English units on bottom and left side).

directly with the speed, given by the equation $Y = 74S$, in which Y is the percentage increase in heat production and S is speed of walking in miles per hour. At one mile per hour, the heat production is 74 per cent above standing; at two miles per hour, it is 148 per cent above standing, and so on. The

²⁹ Smith, H. M., Carnegie Inst. Wash. Publ., 309, 1922.

percentage increase in cattle is of the same order as in man, but in horses it is less than in man.

As regards the caloric cost of walking, the upper chart in Fig. 24.8b shows that the overall cost (including the rest-maintenance component) per unit live weight decreases with increasing speed approaching 39.7 Calories per 100 lb. per mile as limit, as indicated by the equation

$$Y = 44e^{-0.368S} + 39.7$$

in which Y is Cal/100 lb wt/mile, and S is speed of walking. The higher the speed the less the overhead charge per unit ground covered and, therefore, the less the overall cost. If, however, the rest-maintenance item is not included in the total cost, the cost of walking is independent of speed. In terms of Calories per 100 lb live weight this *net*³⁰ energy of walking one mile is, in round numbers, 40 for humans, 33 for cattle, and 28 for horses. (In terms of gm-cal per kg-m it is 0.544 for humans, 0.452 for cattle, and 0.385 for horses.) These values (per unit live weight and per unit horizontal distance walked) are apparently independent of live weight for a given species and given state of fatness. Horses spend less energy moving unit body weight per unit horizontal distance than humans or cows. Cows and humans spend almost the same amounts of energy per unit live weight and unit distance. Fasting decreased metabolism both during standing and walking, but the percentage increase due to walking tended to increase with increasing time after feeding.

Summarizing, this section defines the units of work, rate of work, and energetic efficiency and presents methods for measuring them. Extensive data and generalizations (equations) are presented on the absolute and relative energy costs of standing, walking at various speeds, and working at various rates by varying load and speed. The immediate and long-range energetic efficiencies of various categories of work machines were compared critically.

24.3: Relative metabolism in steady, maximum, and brief peak effort. The rate of oxygen consumption or heat production is, of course, a function, among other factors, of body weight and work rate. The statement that an animal consumes oxygen at the rate, for example, of $\frac{1}{4}$ liter/min or produces heat at the rate of 1.2 Cal/min is, therefore, ambiguous unless given with reference to some standard size and work rate. In this section we shall take the resting oxygen consumption (approximately $\frac{1}{4}$ liter/min for adult male man) as reference base and express other values as multiples of this reference base. In the preceding section it was shown that the energy cost of walking is about 100 per cent above that of standing; that the ratio energy expense of walking/energy expense of standing = 2, and that this ratio is approximately the same in relatively large and small animals, horses, cattle, sheep, men. In this section we shall consider similar ratios for various work levels.

³⁰ The net energy cost of walking does not include the energy cost of standing at rest, while the overall or total energy cost does.

24.3.1: Ratio of maximum to minimum oxygen consumption in horses and men. Fig. 24.9a shows ratios of maximum to minimum oxygen consumption in horses plotted against speed, load or draft, and horse power. The ratios of work oxygen to *resting* (not basal) oxygen increase to about 15, while the

Fig. 24.9a. Ratio of work to rest oxygen on left side, and ratio of work to basal oxygen on right side plotted against speed, load, and work rate (horse-power). These ratios do not include possible "oxygen debt", therefore, they are not peak-efforts of which animals are capable (including oxygen debt), but ratios of maximum to minimum oxygen consumption.

Fig. 24.9b. Overall efficiency as function of the work to rest energy ratio.

ratios of work oxygen to *basal*-metabolism oxygen increase to about 21. Since the top values represent work near the maximum of the animal's ability under the given conditions, it is concluded that the maximum amount of oxygen that

a work horse can utilize is about 21 times the minimum or basal oxygen.³¹

According to Dill³² the ratio of maximum oxygen consumption by men running at top speed to basal oxygen consumption varies from 10 to 20, depending on physical development and training. We, therefore, conclude that our 1500-pound work horse in excellent physical condition had approximately the same ratio of maximum to minimum oxygen consumption as a man in excellent condition. The ratio of work to resting oxygen consumption is apparently independent of size or even species; which means that in comparison to body weight, the limiting system concerned with supplying the muscles with oxygen is of the same relative capacity in superior work-horses as in superior athletic men. Race horses of extraordinary physical development and training probably have higher ratios than men or work horses. This is an attractive problem for study.

Data by Sargent³³ indicate that the maximal oxygen intake was 15-fold resting in a 63-kilo athlete. Schneider and Clark³⁴ reported (on R. W. C.) a 10-fold oxygen consumption when working a bicycle ergometer 8000 foot-pounds per minute (2.66 liters oxygen per minute) than at rest (0.282 liters per minute). Hill's tabulation³⁵ shows that a 184-pound oarsman (H) consumed 4.41 liters oxygen per minute; 147-pound runner (S) consumed 4.38 liters oxygen per minute. These oxygen consumptions correspond roughly to 1323 and 1314 Cal per hour. Assuming basal metabolism levels of 76 and 65 Cal per hour, the ratios of maximum to basal energy are 17 and 20, thus substantiating Dill's conclusion that the oxygen supply to the tissues is limited to about 20 times basal metabolism.

More recently Dill³⁶ observed a famous 2-miler, Lash, consume 5.35 liters oxygen, 21.4 times the basal level (of $\frac{1}{2}$ liter O_2 /min), when running at the rate of 21.6 km/h, approximately the pace that he runs in his 2-mile winning races. This is said to be the highest oxygen-consumption record,³⁷ and contrasts to 14.5 times the basal level of oxygen consumption in the best untrained controls. This high rate of oxygen consumption is attributed to the extremely high cardiac output since the oxygen-carrying capacity of the blood was virtually the same as in the non-athletes. Incidentally, the highest pulse rate was 189 and the blood lactic acid 73 mgm per cent. At a lower work rate, 11.3 km/h on an 8.6 per cent grade, the athlete's pulse rate rose to 171 and the non-athletes' to 190.

The ratio of the work to resting oxygen consumption may be used for estimating physiological work-equivalence in different animals. Thus from Fig. 24.9a, when the ratio work O_2 /basal metabolism O_2 is 10, work in the Shetland pony at the rate of 0.6 H.P. is equivalent to work in the Percheron horse at the rate of 1.4 H.P., and so on.

³¹ In preparing Fig. 24.9 it was assumed that the basal metabolism of the 1500-lb. horse is 400 Cal per hour (see Table 13.7); the standing metabolism, including the normal heat increment of feeding, 606 Cal/hr.

24.3.2: Ratio of maximum effort, including the oxygen debt, to rest energy in men and horses. The preceding discussion was concerned not with peak-effort *energy expenditure*, but with peak-effort *oxygen-consumption*. The maximum energy expenditure is very much greater than the corresponding maximum oxygen consumption because (Sect. 6.2), animals (unlike engines) go into *oxygen debt* in emergencies and repay it later during rest. Athletes have been known to incur an oxygen debt of 8 liters during 15 seconds of sprinting at top speed. Such intense anaerobic efforts can last only a few seconds but are of tremendous value in emergencies. The ability to go into oxygen debt varies; great athletes usually have exceptionally high abilities in this direction. Superior race horses may be able to incur a greater oxygen debt than inferior ones. How does peak-effort energy to basal energy in man differ from that in the work horse?

The following table, based on the 1925 Iowa State Fair horse-pulling contest, indicates the order of peak effort in the winning heavy-weight teams.³³

Trial	Distance pulled (feet)	Duration of trial (seconds)	Tractive pull (pounds)	Horse-power
1	27½	4.0	2000	25.0
2	27½	4.2	2500	29.8
3	27½	11.0	3000	13.6
4	27½	8.0	3200	20.0
5	27½	11.0	3400	15.5
6	27½	9.8	3425	17.5

Since the teams were made up of two horses, the rates of energy expenditure per horse are half the above values, 7 to 13 H.P. This table shows, then, that a 1500-pound horse can develop 7 to 13 H.P. during about 5 seconds. Assuming that the energetic efficiency of the pull is 20 per cent, the horses expended energy at the rate of 35 to 65 H.P. or (since 1 H.P. is equivalent to 10.7 Cal/min) 375 to 803 Cal/min. Since the basal metabolism energy of a 1500-pound horse is about 7 Cal/min, the ratio of peak energy expenditure to basal metabolism energy in the horse is $375/7$ to $803/7 = 53$ to 115. In brief, *a work horse is capable of spending about 100 times as much energy at maximal effort (for a few seconds) as during rest.*

As previously noted (Sect. 6.2) Fenn reported that a medical student performed at the rate of 139 Cal/min. If his basal metabolism was 1.2 Cal/min, the ratio of peak energy expenditure to basal energy was $139/1.2 = 116$.

24.3.3: Ratio of sustained hard work to rest energy in men and horses. According to Dill,³² the ratio of sustained-work energy (as is carried on in the usual 8–10 hour day) to basal-metabolism energy ranges in man from 3 to 8 in hard work (lumbering, building, mining, agriculture) to less than 3 for moderate work. How do these ratios for humans compare to those in horses?

³³ Collins and Caine.²²

As previously noted, a good pace for a 1500-lb. farm horse is work at the rate of 1 H.P. From Fig. 24.9a, the work to basal-metabolism energy ratio for a 1500-lb horse working at the rate of 1 H.P. is of the order of 8, which is the same as that given by Dill for human labor at hard work. Hence, the conclusion that the ratio of sustained hard work to rest energy is approximately the same in horse and man, and probably independent of size or even of species as such. Note from Fig. 24.9b how the overall efficiency for Horse 19 flattens sharply when the work-to-rest ratio is between 5 and 8.

Fig. 24.10a. Energy expended per day (24 hours) plotted against ratios of work energy to: basal energy and to non-basal resting energy when the horse works 0, 2, 4, 6, 8, 10, 12, and 24 hours per day, and stands the remainder of the time.

The energy expended per 24-hour day, including the resting periods, is for humans from about 3000 Calories for moderate work to 6000 Calories for hard work (when the work to rest energy is near 8); that is, from 1.3 to 4 times the basal energy. It is instructive to know how the 24-hour energy expenditure in horses varies with the number of hours worked when working at different

rates. From Fig. 24.10a, when the 1500-lb horse works 8 hours a day at a work-to-basal metabolism ratio of 8, he performs at the rate of about 1 H.P., and expends energy at the rate of 38,000 Calories per 24-hour day, corresponding to 21-lb *TDN*. At this rate of work the 1500-lb horse expends $38000/6000 = 6$ to 7 times as much energy as a 150-lb man; which is what might be expected on the basis of the assumption that average work rate and energy expense vary with $W^{0.73}$. Similar curves are given in Fig. 24.10b for horses working 2, 4, 6, 10, and 12 out of the whole 24 hours.

Fig. 24.10b. Overall efficiency as function of horse-power. Upper chart represents full-time work for the 3 speeds; lower chart represents part-time work, i.e., 2, 4, 6, 8, 10, and 12 hours work out of 24, all speeds combined.

Summarizing this section, 1) the rate of oxygen consumption during average walking is, approximately, double that of standing; 2) the oxygen consumption of sustained heavy work (6–10 hours/day) is 3- to 8-fold rest; 3) the *maximal oxygen consumption* is, approximately, 20-fold resting; 4) the *maximal energy*

expenditure during maximal exertion for a few seconds is about 100-fold rest. These ratios are the same for 1500-lb and 750-lb horses as for 150-lb man; they are independent of body weight and perhaps of species *as such*. There are, however, considerable individual variations in this respect, and training greatly influences these ratios.

Fig. 24.10c. All-day efficiency and profit plotted against hours worked at 1 H.P. per day.

24.4: Mechanisms limiting work capacity. Muscular-work capacity is dependent on many factors such as on soundness of limbs and muscles, on body build and strength, on skill and intelligence, on temperament and ambition, and so on. These factors are more or less judgeable externally, by inspection. There are, however, also factors and aptitudes which are not externally evident, measurable only functionally. These are concerned mostly with the oxygen supply to the tissues by the cardio-respiratory system.

A distinguishing feature of animals is the onset of fatigue with increasing work, and the greater the speed of work, the more rapid the onset of fatigue. Progressive fatigue absent in "running" engines is the most conspicuous feature in running animals. A good racing horse can run a quarter mile (in 23 seconds) at the rate of 39 miles an hour but can never run all of the 39 miles in an hour because of encroaching fatigue after the first 30 second's run.

The speed of onset of fatigue³⁹ is, perhaps, the best measure of lack of work capacity and of disease. Disease has indeed been defined by impairment of work capacity.⁴⁰ Muscular work involves so many structures and functions that impairment of one of these or disturbance of the integration between them increases the speed of onset of fatigue and decreases work capacity. On the other hand, a limiting organ or function may be seriously diseased, yet the individual and observer may be unaware of it because of the masking effect of a compensatory mechanism that takes over for the duration. One organ or function may be maintained at the cost of impairment of another. Compensation may thus be associated with decompensation. Athletes sometime die when apparently in their prime because of the presence of such unsuspected, masked, serious disease.

Assuming, for the present, that muscular-work capacity is ultimately limited by the rate and efficiency of oxygen supply, one may estimate work capacity by functional tests of the several systems involved in supplying oxygen to the tissues as discussed below.

24.4.1: Pulmonary ventilation. The exhaled air per breath, "tidal air,"⁴¹ is the capacity factor. The respiration rate is the intensity factor. If the resting tidal air is 1 liter and the resting respiration rate is 10/min, the resting pulmonary ventilation is 10 lit/min, or the minute volume of pulmonary ventilation is 10 liters. On collapsing one of the lungs the tidal air may be halved

³⁹ In a $1\frac{1}{4}$ -mile race, one horse ran the first and second quarter miles at 24.25 sec each; the third quarter mile at 24.86 sec; the fourth at 25.62 sec; the fifth at 26.05. Blake, L. L., and Brownlee, R. B., "Race horse and race track speed, an analysis of racing records." Preliminary edition, 1936, by L. L. Blake, Standard Statistics Co., 345 Hudson St., New York, N. Y. The mile record (1942) for a horse is 1:34 $\frac{1}{2}$ made by two-year-old Count Fleet. Maximal speeds are said to be run at the rate of 22 miles/hr for man (Jesse Owen ran 100 meters, that is 328 feet, at the rate 21.7 mile/hr); horse, ass, dog, 37 mile/hr (race horses have been known to run $\frac{1}{4}$ mile at the rate of 44 mile/hr). Flying is, of course, more rapid: ranging from the golden eagle 120 mile/hr, duck hawk 180 mi/hr, deer bat fly 450 mile/hr, comparable to that of an airplane. For data and literature on "Flight speed of birds," see M. T. Cooke, U. S. Dept. Agr. Cir., 428, 1937.

⁴⁰ Simonson, E., and Enzer, N., *Medicine*, **21**, 345 (1942).

⁴¹ The *vital capacity* is the largest volume of air exhaled following the deepest inhalation. *Vital capacity* = tidal air + supplemental air. The *alveolar air*, in contact with the respiratory epithelium, is the sum of the *supplemental* and the *residual* (non-exhalable) air. The alveolar air is richer in CO₂ and poorer in O₂ than tidal air. Alveolar air in man contains 4.5-6.5% CO₂, 13-15% O₂, 80% N₂, and is completely saturated with H₂O. Pulmonary capacities cited from Dill, *et al. Science*, **85**, 409 (1937): vital capacity, 5.4 liters in athletes and 4.7 liters in non-athletic young men. Tidal air, 2.4 liters in athletes and 2.3 liters in non-athletes. Tidal air is thus 46% of the vital capacity. For a given oxygen consumption, the athletes' ventilation rate was 12% less than of the other subjects. Pulmonary ventilation at maximal work was 113 liters per minute in the athletes and 98 liters per minute in non-athletes. The respiration rate at this maximal work was 48 in the athletes and 44 in the non-athletes. The ratio of residual air to total lung volume was 0.288 in the athletes and 0.285 in the non-athletes. Most published observations on non-athletic college students at rest cite tidal air $\frac{1}{2}$ liter, vital capacity 4 liters, respiration rate 16/min. pulmonary ventilation 8-10 lit/min. Training athletic men reduces the resting respiration rate to 10/min. The values vary with size. Women, therefore, usually have lower tidal air and pulmonary ventilation.

and the respiration rate doubled, thus maintaining the previous ventilation rate of 10 lit/min.

This compensation of the halving of the capacity factor by doubling the intensity factor occurs at an extra energy cost involved in doubling the rate of chest movement for a given ventilation rate. The chest moves twice as rapidly and fatigues more rapidly.

Moreover, the compensated pulmonary system lost half of its *reserve capacity*, its safety margin, so that the compensation has been achieved only for rest or for lower work levels. The reserve is lost for higher work levels or for disease, such as for pneumonia, emphysema (in which the diffusion of oxygen through the lungs is reduced) and with the loss of the margin of safety, life becomes correspondingly more circumscribed.

This discussion shows that *the lung capacity (tidal air) at a given metabolic rate and a given temperature is inversely proportional to the respiration rate*. It is important to specify temperature because the pulmonary ventilation also has a temperature-regulating function in slightly-sweating animals above 30°C (85°F). The respiration rate increases rapidly with increasing environmental temperature in most farm animals (but not in man). The more rapid hot-weather breathing (panting) is, however, shallowed so as to maintain the ventilation rate constant (Sect. 11.5).

24.4.2: Blood circulation. In blood circulation the pulse rate is the intensity factor and the systolic output (stroke volume) is the capacity factor, corresponding, respectively, to respiration rate and tidal air in pulmonary ventilation; and the *heart capacity* (systolic output = volume of blood ejected by a contraction or systole of the left heart or ventricle) *at a given metabolic rate* (also at a given temperature and a given emotional status) *is inversely proportional to the pulse rate*.

The average resting pulse rate in adult man is approximately 70; the lowest, usually found in great athletes, is approximately 40, although one athlete, Les MacMitchell, said that his resting pulse has been at one time 31 per minute.⁴² Low pulse rate is, then, in general, an index of an efficiently-functioning, powerfully-contracting heart and, therefore, probably of great work capacity. Conversely, the smaller the systolic output, that is the less blood ejected per contraction, the more rapid must be the pulse or the heart contractions to maintain the normal circulation rate, the less efficient it is, the more easily fatigued, the less reserve it has, and consequently the smaller the work capacity.

The mechanical work of and the energy expended by the heart: The average man's heart weighs about 1½ lb and delivers blood at the rate of about 4 lit/min at rest and, perhaps, 40 lit/min during maximal exertion. The work rate of the heart is, of course

⁴² White, P. D., *J. A. M. A.*, 120, 642 (1942): the basal pulse rates of five men were: 38, 38, 37, 37, 35, belonging, respectively, to a marathon runner, an aviator, a champion miler, a non-athletic middle-aged man with slight hypertension, with a cardiac enlargement, a champion miler. Cunningham's pulse was reported to be between 40 and 45, Les MacMitchell's 37, and Nurmi's 40.

the product of the blood quantity ejected and the systolic pressure.⁴⁴ Thus (Hill, Long and Lupton) if the cardiac output is 40 liters/min and the systolic pressure is 100 mm Hg, the work by the ventricle (left side of the heart) is $40 \times 100/760 = 5.3$ liters-atmospheres per minute = 128 Cal/min. Assuming an efficiency of 20 per cent, the energy expenditure by the left side of the heart is 640 Cal/min. Adding 25 per cent for energy expended by the right side, the total expended by the heart is 800 Cal/min, equivalent to 160 cc O₂/min. Assuming a 60 per cent O₂ utilization coefficient and a blood oxygen capacity of 18.5, the coronary vessels would have to supply to the heart tissues 1.5 liters blood per minute. Hill cites an example of the consumption of 5.9 liters of oxygen per minute involving a total heart output of 75 liters—17 gallons—of blood per minute, a work rate of 631 foot-pounds per minute or 0.02 H.P.

As noted above, the average man's systolic output at rest is 60 cc and the pulse rate is 67, so that in one minute the ventricle ejects $60 \text{ cc} \times 67 = 4000 \text{ cc}$, or 4 liters blood.

During maximal exertion, the cardiac output⁴⁴ is increased tenfold, to an approximate maximum of about 40 liters. The pulse, too, increases with increasing work rate; it may increase to 180 at maximal exertion in which the maximal systolic output may reach $40000 \text{ cc}/180 = 222 \text{ cc}$, which is near the theoretical maximum since the anatomic volume of the pericardium is, in man, not over 700 cc and the volume of the left heart cannot be over $\frac{1}{3}$ of the pericardial volume, about 230 cc. It is said that the systolic output is increased as result of training, so that more blood is pumped per minute with fewer beats for a given oxygen consumption. Training affects the entire cardio-respiratory system.⁴⁵ In one case (Knehr, et al⁴⁵) training 6 months reduced the pulse rate from 67 to 62, respiration rate from 15.1 to 14.3, pulmonary ventilation from 6.2 to 5.7 lit/min; oxygen capacity was increased from 19.8 to 20.2 and plasma chlorides from 103.6 to 105.8.

Needless to say that in addition to the left side of the heart, the ventricle, the blood also has to pass through the right side of the heart; so that the heart as a whole ejects what virtually amounts to not 4.0 but 8.0 (over 2 gallons) liters per minute at rest and not 40 but 80 liters (over 20 gallons) per minute at maximal exertion. This surprising maximal value is, of course, achievable only by rare athletes.

24.4.3: The blood.⁴⁶ With the aid of its hemoglobin, blood carries oxygen to and carbon dioxide from the tissues to the lungs where the carbon dioxide

⁴⁴ *Definitions: Systole*, period of contraction and discharge of the blood; *diastole*, period of relaxation and refilling with blood; *systolic pressure*, maximum blood pressure during the systole; *diastolic pressure*, about $\frac{1}{3}$ of the systolic pressure, minimum pressure between the heart beats at the end of the diastole. *Pulse pressure*, difference between the systolic and diastolic pressure. The *systolic output* is a function of the product of the pulse pressure and pulse rate. The systolic pressure in adult man is 100 to 150 mm; diastolic, 65–90; pulse pressure 35–55; capillary pressure 15–40.

⁴⁵ Grollman, A., "The cardiac output of man in health and disease." Thomas, 1932.

⁴⁶ Steinhaus, A. H., *Physiol. Rev.*, **13**, 103 (1933). Dill, D. B., and Brouha, L., *Le travail humain*, **5** (1937). Christensen, E. H., *Ergeb. d. Physiol.*, **39**, 348 (1937). Taylor, C., *Am. J. Physiol.*, **135**, 27 (1941). Robinson, S., and Norman, P. M., *Am. J. Physiol.*, **133**, 168 (1941). Knehr, A., Dill, D. B., and Neufeld, W., *Id.*, **136**, 148 (1942).

⁴⁶ The published blood volume is highly variable, perhaps 6% to 7% of the body weight, perhaps 5 liters in the average man's body. The fatter the individual the smaller the relative blood volume; the more muscular and the thinner, the greater the relative blood volume. Blood contains about 5 million red cells and about 8000 white cells per cubic mm, more in athletes, less in sedentary. Arterial blood contains about 19% O₂, 50% CO₂; venous blood, about 14% O₂ and 55% CO₂. The alkaline reserve—the bicarbonate CO₂ obtained from blood previously saturated with CO₂ at a partial pressure of 40 mm Hg—is 50 to 80 volume per cent. The blood hemoglobin ranges from 10 to 12% in non-athletes to 15% in athletes or athletic animals. A gram hemoglobin combines with 1.34 cc O₂ so that on saturation blood contains about 20 cc O₂ (for details, see Sect. 6.4.2).

is released and the oxygen taken on. The blood makes the circuit in about a minute, the exact speed depends on body size and metabolic rate.

When the blood becomes oxygenated in the lungs, it is 90 to 95 per cent saturated with oxygen, containing 17 to 20 cc oxygen per 100 cc of blood, more or less depending on the hemoglobin concentration.⁴⁶ After the blood has unloaded the oxygen to the tissues, its oxygen saturation is about 30 percent; so that the blood gives off about 60 per cent of its oxygen; 60 per cent of 20 = 12 cc oxygen per 100 cc blood. At rest, 100 cc blood may unload only 30 per cent or 5 to 6 cc oxygen; during maximal exercise in well-trained athletes, it may unload 70 per cent or 15 cc oxygen.

The intensity factor of the blood is, then, the arterio-venous oxygen difference; the capacity factor, the amount of hemoglobin.⁴⁶ The coefficient of oxygen utilization (Krogh) is the ratio of the arterio-venous difference (or oxygen transport) to volume percent of oxygen in the blood (oxygen capacity).

A high blood capacity like a large pulmonary or cardiac capacity indicates a large oxygen-reserve power. Diving animals,⁴⁷ some of which (whales) can remain submerged 2 hours, or even those (beavers, seals) that can remain submerged for one-half hour have unusually large blood volumes and hemoglobin concentrations, including muscle hemoglobin, perhaps double those of non-diving species. High-altitude dwellers⁴⁸ (such as the llama, vicuna, S. American ostrich, and native man, too) have larger quantities of hemoglobin than low-altitude dwellers. But, as previously noted, individuals within the species and under the same conditions also differ in their hemoglobin content and in the percentage of oxygen they can unload on their circuit (for fuller discussion see Sect. 6.4.2).

24.4.4: Oxygen debt. As previously explained (Ch. 6), biologic oxidation is a stepwise process, the initial stages of which do not involve the participation of oxygen, illustrated by the (anaerobic) conversion of glucose to lactic acid. When, therefore, in maximal exertion for several seconds (as in the 60-yard dash in man, $\frac{1}{4}$ miles dash in the horse, or in the 10-second horse-pulling contest) the energy expenditure is perhaps five-fold the maximal capacity of oxygen supply, the energy is obtained from anaerobic oxidation. Intermediate products are formed (lactic, phosphoric, and pyruvic acids) which are oxidized during the recovery phase. Phosphocreatine and adenosine pyrophosphate are also decreased during the exercise and reformed during the recovery. The oxygen debt is, then, measured by the oxygen increment above normal rest oxygen consumption during the recovery or resting phase. The oxygen debt is known (Ch. 6) to have risen in a 70-kg athlete to 19 liters and the lactic acid to 114 gm ($\frac{1}{4}$ lb) or to 0.32 per cent. (The lactic acid content in resting human blood is 0.01–0.02 per cent.) One liter

of the oxygen increment consumed during recovery is often assumed to be equivalent to the removal of 7 to 8 gm lactic acid or to its re-conversion to glycogen, although the oxygen debt may be alactic.⁴⁹

Athletes (also diving animals and mountain dwellers) are thus distinguished not only for their ability to perform much work without going into oxygen debt but also to go into great oxygen debt when the necessity arises. They are thus provided with two supplementary reserves or mechanisms for survival in oxygen-lack emergencies.

24.4.5: Coronary circulation. The astonishingly high rate of work the heart is capable of performing, pumping 40 liters of blood a minute against a very considerable pressure, is, of course, conditioned on a heart muscle well supplied with oxygen as well as with fuel. As indicated by Hill's data cited above, the heart must have for its own use alone, at maximal work, not less than 1.5 liters of blood a minute (assuming a 60 per cent oxygen utilization). This special blood supply for nourishing the heart muscle itself is furnished by the coronary arteries. If the coronary arteries develop a defect, the work capacity of the heart muscle is correspondingly reduced—the heart cannot work without a plentiful oxygen (blood) supply. Attempt to work with an inadequate coronary blood supply results in inadequate oxygenation, in ischemia of parts of the heart muscle which gives—to persons whose nerves are sensitive to such sensations—the “heart” pain, angina pectoris. As this pain is frequently localized in the pit of the stomach, it is sometimes mistaken for “acute indigestion” in man or “colic” in horses. Some sufferers from inadequate coronary circulation are apparently insensitive to ischemic pain signals and die suddenly, without warning, on some sudden exertion, or excitement, or over-eating (especially on fermentable forage or food).

It is obvious that athletes and others, such as race horses and dogs, indulging in maximal effort must be endowed with phenomenal coronary-artery systems although sudden death in athletes and race horses may occur due either to accidental coronary obstruction (coronary thrombosis) or to insensitiveness to anginal pains which keeps them ignorant of their coronary inadequacy, leading to exertion beyond their cardiac capacity.

The coronary arteries tend to deteriorate with increasing age⁵⁰ although very aged individuals often have youthfully-appearing and functioning coronaries. Indeed, the youthful coronaries may be the reason for their survival to an advanced age. The early deterioration of the coronaries may depend not only on their hereditary quality but also on the neuroendocrine system which controls the caliber of these arteries. This is inferred from the large incidence of early coronary damage in highly-strung individuals. Overproduction of adrenalin is said to be an influencing factor (Raab). Excessive dietary fat,

⁵⁰ Robinson, S., *Arbeitsphysiol.*, **10**, 251 (1938).

especially rich in cholesterol, is said to produce atherosclerosis⁵¹ (rather than arteriosclerosis).

24.4.6: Body-temperature regulation.⁵² Hard muscular work is, of course, associated with correspondingly rapid heat production, thus placing the temperature-regulating mechanisms under stress. The extra heat dissipation is associated with the shunting of blood to the surface, leaving less blood in the interior, with consequent increase in pulse rate which may lead to heart failure (heat exhaustion, heat stroke, sun stroke). "Heat cramps," muscular pains, are associated with loss of salt in the sweat.

The cooler the environmental temperature, within limits, the lower the strain of heat dissipation and, therefore, the higher the attainable work rate. Conversely, the higher environmental temperatures, especially above 30°C (85°F), are less favorable for hard work and indeed dangerous at the later ages (Chs. 11 and 18).

24.4.7: Nutrition. It is believed that carbohydrate is the best fuel for muscular work. The superiority of carbohydrate to fat as fuel is due to several factors, including, 1) greater readiness of mobilization of carbohydrate for muscular work; 2) about 7 per cent less oxygen is required to obtain unit energy from carbohydrate than fat (the thermal equivalent per liter oxygen is 5.05 for carbohydrate and 4.69 for fat); 3) it is believed⁵³ that before oxidation for muscular work, fat is converted to carbohydrate, involving a 10 per cent energy loss in the conversion. (Hill⁵⁴ believes that for peak effort carbohydrate is the only fuel.) Whatever the theory, Christensen⁵⁵ observed that men engaged in "steady-state" maximal work succeeded in continuing the work for 4 hours on a high carbohydrate diet, but only 1½ hours on a high fat diet. Moreover, an hour of such work on the high fat diet was followed by accumulation of acetone bodies in the blood.⁵⁶ Dill⁵⁷ observed that a dog could run on a treadmill 17 hours when supplied with glucose, but only 4 hours when not so supplied, and compelled to live on body fat. The blood sugar of the dog not receiving glucose reached the low level of 50–60 mg per cent at the time of exhaustion, about half the normal blood-sugar level.

There is no general agreement on the question as to whether fat can be used as muscle fuel⁵⁸ nor on the optimal carbohydrate-to-fat proportions in the body-

fuel mix. Henderson and Haggard⁵⁹ reported that fat furnished about $\frac{2}{3}$ of the energy expended by their Yale oarsmen; that is, sugar is not the sole fuel of muscular energy. However, they believe that sugar is the fuel most immediately available for muscular work and that it would be helpful to the "wind" and for avoiding overtraining if athletes were furnished enough carbohydrates to maintain an R.Q. of 0.85 to 0.9 (when carbohydrates would contribute 50 per cent to 65 per cent of the total energy).

These authors quote approvingly the well-known dictum⁶⁰ that "in the living body, fat burns only in the flame of sugar," meaning that with deficiency of sugar, oxidation of fat is incomplete. They suggest that it would be advantageous to raise the R.Q. by "eating a quarter of a pound of some simple candy, such as peppermint creams, a half to three-quarters of an hour before any prolonged contest" (Sect. 7.6).

Dill⁶¹ does not think that there is carbohydrate deficiency in blood under ordinary conditions of hard sustained work.⁶² This he infers from the fact that steel workers show no symptoms of ketosis, the usual test for fat preponderance (i.e., carbohydrate deficiency) in the oxidation mix; he attributes the favorable effect of refreshments in mid-morning and mid-afternoon⁶³ to psychological rather than nutritional factors. However, heavy work, especially under conditions of emergency, makes heavy inroads on the carbohydrate level, and glucose intake should be very helpful. The collapse of marathon runners has often been attributed to carbohydrate depletion.⁶⁴

Recently publicity was given by gelatin manufacturers to a report that gelatin (washed down with orange juice) increased the work capacity of bicycle riders.⁶⁵ This research was motivated by that fact that $\frac{1}{4}$ of gelatin is glycine and that glycine enters into phosphocreatine which is supposed to furnish energy for muscular contraction (Ch. 6). However, all proteins are rich in glycine (Sect. 20.7), vigorous muscular exercise can take place when the phosphocreatine concentration is very low, and recent data do not indicate that gelatine is helpful in muscular contraction.⁶⁶

Vitamin C may become a limiting factor in muscular work because, like

Chem.*, **47**, 433 and 449 (1921); **49**, 143 (1921); **54**, 399 (1922); **61**, 585 (1924); **66**, 63 (1925); at least $\frac{1}{2}$ molecule of glucose must be oxidized for each molecule of fatty acid or acetoacetic acid; if less glucose is available, the fat oxidation stops at the acetoacetic acid stage. Glucose-forming amino acids and glycerol are, like glucose, antiketogenic, but to a smaller extent. Certain amino acids (such as tyrosine, phenylalanine, leucine) are, like fats, ketogenic.

salt,⁶⁷ it is lost in sweat and deficiency may cause muscle pains during strenuous work.⁶⁸ The pains were relieved by feeding 300 mg ascorbic acid a day (contrasted to the "standard" 75 mg). Horses synthesize ascorbic acid but perhaps not sufficient for their needs under conditions of prolonged hard work in a hot climate. A common salt solution of 0.9 per cent is the usual prophylactic against excessive salt loss in the sweat of hard working man in hot environments, which causes muscular pain (heat cramp).

The need for oxidation-reduction vitamins (Ch. 6) in general tends to be directly proportional to the rate of work, that is to the rate of oxygen consumption. Thiamine is a conspicuous member in this category. Other methods of improving performance are widely but fruitlessly discussed.⁶⁹

In this connection a word may be said concerning hormone administration. Thyroid administration to a hypothyroid animal will, of course, increase its work capacity; but its administration to normal animals is likely to decrease work capacity. It is known that the energy cost of work is much higher and efficiency lower in hyperthyroid than in normal individuals,⁷⁰ perhaps because of the high circulation rate in the hyperthyroid.

Likewise, as regards adrenal hormones. The administration of adrenalin to adrenal demedullated rats or to adrenalectomized rats treated with either adrenal steroid or glucose increased the rate of work of rats;⁷¹ but it is not certain that adrenal-cortex administration to normal animals modifies work ability, willingness, or efficiency.⁷² Nor is benzedrine or amphetamine, a drug related to adrenalin and widely publicized for its effect on "intelligence," helpful.⁷³ Adrenalin may, however, facilitate carbohydrate utilization. Its administration to a *fasting* man working at a moderate rate increased carbohydrate utilization "more than one-half over the corresponding period in the control experiment."⁷⁴

24.5: Measuring work capacity. The preceding section discussed the factors which, singly or in combination, limit work capacity: pulmonary ventilation, blood circulation, oxygen capacity of blood, oxygen debt, coronary circulation, body-temperature regulation, nutrition. Some of these factors

were resolved into capacity and intensity components. Stamina, reserve power, endurance appear to be directly proportional to the capacity components of these factors, such as to systolic blood output, tidal air exhalation, quantity of hemoglobin (blood), caliber of the coronary vessels. Some of these components, such as tidal air, respiration rate, and pulse rate are easily measured. Perhaps the most important of these, namely systolic output, is not easily measured in horses, and not even in man.⁷⁵ As a result, attempts were made to estimate indirectly the systolic output and circulatory conditions based on some reasonable assumption, such as that the systolic blood output is directly proportional to the pulse pressure (difference between systolic and diastolic pressures), and that the circulation trend is proportional to the product of pulse pressure and pulse rate, as indicated by the equation⁷⁶

$$\text{Circulation-rate index} = \text{pulse pressure} \times \text{pulse rate}$$

or by a modification of the above as:⁷⁷

$$\text{Circulation-rate index} = \frac{\text{pulse pressure} \times \text{pulse rate}}{\text{arterial pressure}}$$

The above index is in fair agreement with experimentally determined values in normal (but not in cardiac-defective) individuals.⁷⁸

Another such indirect method, widely used, was suggested by Fick (1870) which assumes that the blood output by the heart *per minute* (minute heart volume) is the O₂ consumption per minute divided by the arterio-venous O₂ difference (or the CO₂ production divided by the arterio-venous CO₂ difference); and the systolic output is, then, heart output per minute divided by the pulse rate.

It is clear that we are not yet in a position to estimate the stamina of an animal from each of the component factors. How, then, shall we go about formulating a test of physical capacity?

The most obvious approach is by way of measuring the performance of the body as a whole, integrated performance.

Performance of a given *exercise* is not a good test of stamina because performance also depends on skill (training), intelligence, temperament ("will" to succeed), and so on.

Maximal performance tests for a few seconds, exemplified by the 60-yard sprint by man, $\frac{1}{4}$ -mile sprint by horses, or by horse pulling contests previously described, are tests for neuro-muscular skill and muscular strength but not necessarily stamina or endurance because the energy for maximal exertion for 5 to 30 seconds is derived from anaerobic oxidation, that is, not directly de-

⁷⁵ For exhaustive descriptions of methods and history of measuring systolic output, see Grollman.⁴⁴

pendent on the cardio-respiratory system and yet it may overtax this system and lead to a break-down. The usual dynamometer measures of strength test specialized groups of muscles while stamina and endurance are usually proportional to the cardio-respiratory capacity and to the stability of the nervous system⁷⁹ which controls the pulse rate, blood pressure, distribution of blood and related integrative phenomena. Athletes, improving with training in all the usual strength and skill tests, often suffer nervous break-downs on approach to their apparent prime condition, due to some integrative fault. The body has many compensating or homeostatic mechanisms (Ch. 10); a weak organ or function is often maintained or compensated perhaps at the cost of impairment or decompensation of another organ. This may explain, for example, the occasional rejection of athletes for the military service.

The problem of devising a criterion of physical fitness is a very difficult one, especially in animals who do not cooperate with the investigator. Thus the widely-used Schneider-fitness test,⁸⁰ based on adjustment speed to work and rest, and on standing-lying differences in blood pressure and pulse rate, is not easily applied to horses or other farm or laboratory animals. Moreover, the Schneider test makes but very slight demand on the cardiovascular reserve.^{80a} There is no satisfactory relation between basal pulse rate, sitting pulse rate, and physical fitness for strenuous exertion in normal individuals, and emotional factors have a greater effect on pulse than cardiac reserve.^{80b}

Let us consider possible tests which promise to be applicable to farm and laboratory animals as well as to man.

24.5.1: Maximal oxygen consumption. The maximal steady-state oxygen consumption represents the maximal rate of energy expenditure when the metabolic functions (O_2 consumption, CO_2 production, pulse and respiration rates, ventilation rates, etc.) are steady, that is, constant and, therefore, not involving the incurrence of a cumulative oxygen debt. Reference was made to Robinson, Edwards and Dill who observed a maximum steady-state oxygen consumption of 5.1 liters/minute, 21.4 times basal, in a famous athlete (Lash), as contrasted to 14.5 times basal in the best untrained subject.

In this connection one may note the interesting observation⁸¹ that the car-

⁷⁹ Of all the tissues and systems, the nervous is most sensitive to oxygen lack, illustrated by "blackouts," and dizziness during rapid change in altitude (in airplanes, submarines, elevators, or even on rapid change in position, especially when whirling). One reason for the success of diving animals in remaining submerged in water is that they have mechanisms for hoarding the oxygen and shunting it to the nervous system (see Irving,⁴⁷). The muscles, but not nerves, can get along for sometime without oxygen. The loss of sensitiveness in finger tips, etc., is one of the first signs of an ischemic or anemic condition.

⁸¹ Briggs, H., *J. Physiol.*, **54**, 292 (1920).

bon dioxide percentage in expired air rises with increasing work rate up to a certain work-rate level, then begins to decline. This may be associated with the phenomenon of the "second wind" when, perhaps, the respiratory center in the brain loses its sensitiveness to further CO_2 concentration and perhaps loses control of the CO_2 composition of expired air. Would this inflection in the CO_2 concentration curve serve as a definition of maximal work rate?

For practical purposes maximal steady-state effort may be defined by the maximal work without incurring an oxygen debt.

To illustrate the practical value of knowing the maximal oxygen-consumption rate, one may note that a large fraction of the American population following age 50 years has a maximal oxygen consumption rate twice resting. This means that their maximal exertion cannot exceed that of walking at a moderate rate. This may be contrasted to lumber-camp work involving a steady oxygen consumption eight-fold basal; or steady fast running involving an oxygen consumption of, perhaps, 14-fold basal.

Fig. 24.11. Interrelation between oxygen consumption and pulmonary ventilation. The ventilation rate lags behind the oxygen consumption rate.

24.5.2: Maximal pulmonary ventilation. Since the rate of pulmonary ventilation tends to be proportional (but not linearly, see Fig. 24.11) to the rate of oxygen consumption or carbon dioxide production, the pulmonary ventilation rate may be taken as index of physical fitness. When the maximal

pulmonary ventilation rate is only twice that of rest, the individual is in poor condition. As previously noted,⁴¹ Robinson, Edwards and Dill observed that three great athletes (Lash, Venzke, and San Romain) attained during maximal-effort work a ventilation rate of 113 liters/minute, 15 to 22-fold the average resting ventilation rate of 5 to 8 liters/minute.

Poor condition of the lungs with low rates of oxygen diffusion is compensated by higher pulmonary ventilation rate for a given metabolic rate. The resting ventilation rate in emphysema, asthma, bronchitis, pneumonia may be two to three times that of normal individuals. The *ventilation reserve*⁴²—the difference between the resting and maximal ventilation—is thus less in such patients than in normal individuals.

24.5.3: Rates of adjustment to work and rest and the speed of exhaustion.

It, naturally, takes a little time following the go-signal for the rates of oxygen consumption, pulse, pulmonary-ventilation, blood pressure, etc., to reach the steady state. Likewise, when exercise stops, it takes a little time for the rates

Fig. 21.12. Differences in blood lactate accumulation in 19 men of varying physical ability after 20 minutes exercise expending about ten-fold resting energy. Subjective fatigue feeling paralleled lactate concentration. From D. B. Dill, A. V. Bock, H. T. Edwards and P. H. Kennedy, *J. Indust. Hygiene and Toxicology*, 18, 419 (1936).

of oxygen consumption, pulse, blood pressure, etc. to decline to the starting level. Individuals differ in the rates with which the adjustments are made; and the fitness of the individual, of his homeostatic mechanisms (Ch. 10), may be measured by the adjustment speeds. This is one phase of the Schneider test as it relates to the adjustment of pulse rate and blood pressure (redistribution of the blood flow). The speed of incurrence of and recovery from oxygen debt, acid accumulation, and hypoglycemia, might be included in this recovery-test category.

⁴² Knipping, H. W., *Klin. Wochsch.*, 17, 1097 (1938). Kaltreider, N. L., and McCann, W. S., *J. Clin. Inv.*, 14, 81 (1935). (The pulmonary reserve in emphysema patients is about $\frac{1}{2}$ that of normal individuals.)

Another aspect of the same problem is the tiring speed, which Dill, et al. measured by the blood lactate level after 20 minutes exercise at an energy expense 10-fold that of rest. Fig. 24.12 shows that the blood lactate ranged from 0.1 mM/lit in a famous athlete to 5.0 mM/lit in an individual in poor condition. The subjective feeling of fatigue appeared to parallel the lactate accumulation. The better the condition the higher the cardio-respiratory, the oxygen-supplying, reserve. The accumulation of blood lactate is, of course, due to inadequate oxygenation. The normal resting blood lactate is

Fig. 24.13. Compensation of low systolic output or stroke volume (upper right) by high pulse rate (upper left) and high oxygen utilization (lower left) resulting in a normal minute volume of blood output (lower right).

10 to 20 mg per cent (about 0.1 to 0.2 millimols per liter, since the m.w. of lactic acid is 90.08). A cardiac patient at rest has been reported⁸³ to contain 71 mg per cent lactic acid, and the greater the cardiac disability the greater the blood lactate concentration following a given fairly strenuous exercise. Dill⁸⁴ suggested that exhaustion during work at a high temperature comes when the accumulation of lactic acid in the heart reaches a limiting value.

Cardiac patients may not differ superficially from normals by the rates of oxygen consumption, pulmonary ventilation, or lactic acid accumulation at reasonably low work rates. Thus Fig. 24.13 shows wide differences in systolic output of two individuals, yet virtually the same minute volumes of blood circulation due to the compensatory effects of higher pulse rate and oxygen utilization. The resting pulse rate is, except in special cases, not an index in normal individuals, especially as emotion profoundly affects the pulse.

One of the best available measures of physical fitness is the speed of recovery of the pulse rate following a standard exercise sufficiently intense that no one in the given class can maintain a steady state for over 5 minutes. There is a large literature on this

⁸³ Harris, I., Jones, E. W., and Alfred, C. N., *Quart. J. Med.*, **4**, 407 (1935). Meakins, J., and Long, C. N. H., *J. Clin. Inv.*, **4**, 273 (1927).

⁸⁴ Dill, D. B., Edwards, H. T., Bauer, P. S., and Levenson, E. J., *Arbeitsphysiol.*, **4**, 517 (1931).

type of test,^{84a} the latest being by Brouha and associates, done mostly at the Harvard Fatigue Laboratory^{84b}. As used by these investigators for humans, the subject steps up and down a 20-inch platform 30 times a minute for 5 minutes, unless stopped before by exhaustion. The pulse is counted from 1 to 1½ minutes, 2 to 2½ minutes, 3 to 3½ minutes after work stops. The fitness index is given by the ratio of $100 \times \text{work in seconds}$ to $2 \times \text{sum of heart rates taken 1-1½, 2-2½, and 3-3½ minutes after exercise}$. A ratio below 55 is poor and above 90 is excellent. Needless to say that allowances must be made in this test for differences in size, age, sex, environmental temperature, and so on. We are attempting to use the rate of decline in pulse rate as an index of endurance in jack stock, mules, and horses.

24.5.4: Oxygen pulse per unit weight. Our⁸⁵ research on work-capacity indices has been chiefly concerned with the oxygen pulse per unit body weight.

The *oxygen pulse* is the oxygen consumed per heart beat. The greater the blood volume pumped by the heart per pulse for an animal of a given weight the slower the pulse rate. The oxygen pulse per unit body weight is, then, our index or the systolic output, or heart capacity, which is the usual limiting factor in hard muscular work.

We shall use the following symbols in deriving our oxygen-pulse body-weight equation:

$$\begin{aligned} O_2 &= \text{rate of } O_2 \text{ consumption in cc/min.} \\ f &= \text{pulse rate or frequency per minute.} \\ W &= \text{body weight in Kg.} \end{aligned}$$

The basal oxygen consumption in mature animals of different species, ranging from mice to elephants, is given by the equation (Ch. 13)

$$O_2 = 10.2W^{0.73} \quad (1)$$

Employing Clark's⁸⁶ compilation and analysis of pulse rate data, the corresponding pulse-rate-weight equation is

$$f = 217W^{-0.27} \quad (2)$$

Dividing equation (1) by (2), we obtain

$$\text{Oxygen pulse} = \frac{O_2}{f} = \frac{10.2W^{0.73}}{217W^{-0.27}} = 0.047W^{1.00} \quad (3)$$

indicating that the oxygen pulse, O_2/f , is directly proportional to body weight, to $W^{1.00}$, and not to surface area or to $W^{2/3}$ or $W^{3/4}$. Equation (3) could be derived theoretically, by dimensional analysis (Chs. 13, 17). The graphic relation between O_2 , f , and W is shown in Fig. 24.14a.

⁸⁶ Clark, A. J., "Comparative physiology of the heart." Macmillan, 1927.

Equation (3) may, of course, be written

$$\frac{O_2/f}{W} = 0.05 \quad (4)$$

indicating that the ratio of oxygen pulse to body weight tends to be the same in mature animals of all the species represented by equation (1) and (2), from mice to elephants. If the oxygen-pulse to body weight index is 0.05, the animal probably has an average work capacity; if below 0.05 its work capacity is below the average; if it is above 0.05, its work capacity is above the average.

Fig. 24.14a. Oxygen consumption and pulse rates as functions of body weight.

Fig. 24.14b shows that the oxygen pulse plots practically linearly (the slope on log-log paper is 0.99, nearly 1.0) against body weight and that athletic men, horses, and dogs are above the fitted average line while non-athletic man, beef cattle, "tame" rabbits, and guinea pigs are below the line.

By this type of reasoning, the oxygen pulse, defined by Henderson and Prince⁸⁷ for man alone as the outstanding factor conditioning "total energy which a man can command for the most strenuous moments of life" was generalized by us to include all species, from mice to elephants, a promising tool for comparative bioenergetics, especially for estimating work capacity, particularly under emergency.

⁸⁷ Henderson, Y., and Prince, A. L., *Am. J. Physiol.*, **35**, 106 (1914).

A useful derivation from the oxygen-pulse equation (3) in another connection is

$$\frac{O_2}{W} = 0.05f \quad (5)$$

indicating that the basal oxygen consumption per unit weight in mature animals of different species is directly proportional to the pulse rate; or that the basal

Fig. 24.14b. The oxygen pulse is virtually a linear function of body weight; it is directly proportional to weight (not to surface, etc.). See reference 85.

oxygen consumption in mature animals of different species is directly proportional to the product of weight and pulse rate:

$$O_2 = 0.05fW \quad (6)$$

Returning to the consideration of the oxygen-pulse index, the following table lists values of the resting or basal oxygen pulse per kilo of different animals from mice to elephants. The high values for the mouse, and perhaps rat, is probably without significance because it is difficult to get a mouse to remain quiet and to measure its pulse rate. The relatively high values for athletic men and animals (horses, dogs, cats) as contrasted to the low values for the non-athletic (beef cattle, "tame rabbits," sheep) is highly significant.

Indices of Work Capacity for Different Species.

Species	Oxygen pulse	Oxygen pulse per kg	Data and source from which the indices at left were computed

As previously explained (Sect. 24.5.2), *resting* values of cardio-respiratory capacity may not always be reliable indices of *work* capacity. When we computed⁸⁵ our index values for three members of a Yale crew, from *resting* oxygen consumption and pulse rate data reported by Henderson and Haggard,⁹⁵ we found values around 0.09 for two of the crew, but only 0.05 to 0.06 for the third, the number 7 crew member. Was the low value for this athlete a normal variation (excitement or slight physical disturbance at the time of the test could have altered the relation between pulse rate and oxygen

⁹⁵ Henderson, Y., and Haggard, H. W., *Am. J. Physiol.*, **73**, 193 (1925).

consumption) or was this number 7 crew member able to compete in this strenuous sport despite a relatively low index of work capacity by reason of a superior "will" to win, coupled perhaps with exceptional ability to go into oxygen debt?

Such a question cannot be answered by a study of *resting* indices; more information may be obtained by a study of the behavior of the index under *working* conditions.

Fig. 24.15. The oxygen-pulse trend with increasing work rate. In order to eliminate differences in body size, the oxygen pulse was divided by body weight and the oxygen-consumption rate at given work rates divided by the resting oxygen consumption.

Fig. 24.15, showing curves of oxygen-pulse per kilogram plotted against oxygen ratio or work level (the ratio of oxygen consumed at a given work level to that at the resting level) indicates that athletes (De Mar) have a higher oxygen-pulse-weight index at higher work levels than non-athletes (C.V.C. and D.B.D.), and that horses have higher oxygen-pulse-weight index values than men. These *work* oxygen-pulse-weight indices are very much more useful than *rest* oxygen-pulse-weight indices because they discount differences in ambition, temperament, skill, and also physiologically-compensated conditions at lower but not higher work levels. (Attempts to compare oxygen pulse without correcting for differences in body size and differences in resting oxygen consumption were not successful, as illustrated in Fig. 24.16a.)

Summarizing this section, muscular exercise calls for the integrated action of many functions, any one of which may become limiting in the work capacity complex. On the other hand, serious faults may be compensated or masked by various mechanisms; this explains occasional break-downs of great athletes in their apparent prime. There can, therefore, be no infallible measure of

work capacity. Maximal oxygen consumption, maximum pulmonary ventilation, rapidity of functional adjustment from rest to work and from work to rest are good capacity indices. Special consideration is given to the oxygen consumption per heart beat per unit weight (oxygen pulse per unit weight) as index of work capacity applicable to other species as well as man, *regardless of body weight*. The rational (mathematical) aspects of this index are discussed in detail, and it is shown that the basal metabolism of mature animals of different species is directly proportional to the product of body weight and the basal pulse rate.

Fig. 24.16a. If the oxygen pulse and metabolism are not corrected for differences in body size, the curves are not comparable as here shown. Hence the corrections in Fig. 24.15.

24.6: Relative economy of horse and tractor. The maximum gross energetic efficiency of muscular work in animals, 25 per cent, is at least as great as of tractors (13–19 per cent for ignition and 22–26 per cent for Diesel-type engines). Animals, however, must rest, and all day energetic efficiency and monetary economy vary with the number of working hours (Figs. 24.10a to c). Table 24.3a shows that per horse-power hour, the feed cost is 2.14 cents when the horse works 12 hours a day, 3.5 cents when he works 4 hours a

day, and 5.5 cents when he works 2 hours a day. On the other hand, while the engine does not consume fuel when at rest, the depreciation and interest charges are greater than for the animal, and the working hours per year are fewer for the tractor than for the horse. Tables 24.3b and c from Smith and Jones⁹⁶ support our data in Table 24.3a.

Fig. 24.16b. Blood flow, pulse rate, and systolic output as function of work rate (O_2 consumption).

Comparison between all-day monetary economy of horses and tractors is difficult because of the instability of relative price per unit of tractor and horse fuels. Thus if it is assumed that a pound *TDN* costs 1 cent and contains 2000 Calories, and a gallon kerosene costs 10 cents and contains 41,000

⁹⁶ Smith, D. D., and Jones, M. M., "Power, labor and machine costs in crop production." Univ. Mo. Agr. Exp. Sta. Res. Bull. 197, 1933.

Calories, then *per 1000 Calories*, TDN costs $\frac{1}{2}$ cent and kerosene costs $\frac{1}{4}$ cent. But feed and gasoline prices vary and overhead investments for horses and tractors vary. There are, moreover, many considerations which do not lend themselves to quantitative comparisons, such as income for young stock, utilization of pastures and other feed sources which might otherwise be wasted, superior adaptability of horse, consideration of initial investment with its associated interest payments, smallness of farm for a 12 H.P. tractor, "keeping the money on the farm" and so on. Table 24.3 presents estimates of efficiencies, energy costs, and hypothetical monetary costs and overhead expenses of horse and tractor as far as they can be tabulated, leaving the reader to compare other factors which fluctuate with our rapidly changing economic frame-work.

24.7: Summary. This chapter covers a rather broad territory: the place of the horse in our national economy; the energetic efficiency of the horse in comparison to machines; work levels; energetic cost of muscular work; limiting factor in work capacity; measures of work capacity; relative monetary economy of horses and tractors on the farm. The sections on each of these topics were separately summarized from which the following comments are abstracted.

The maximal gross energetic *efficiency* of muscular work is close to 25 per cent in both 1500-lb horses and 150-lb men: of 100 Calories energy expended (of fuel oxidized in the body during work) not over 25 Calories can be recovered in work accomplished. This 25 per cent maximum efficiency level is approached exponentially with increasing work rate, in accordance with the law of diminishing returns.

The gross⁹⁷ and net⁹⁷ costs of work increase linearly with increasing speed, load, and horse power. The gross and net costs per unit work, or per unit power, decrease hyperbolically with increasing power (Fig. 1.4). But the absolute energy cost is nearly independent of rate of work; it is of the order of 1000 Calories per mega foot-pound (million foot-pounds); or 2000 Calories per horse power-hour (Fig. 1.4). The decline of gross and net cost per unit work with increasing work rate is hyperbolic, the asymptote of which is the absolute-cost curve (Fig. 1.4). The reason for this decline of cost per unit work with increasing work rate is that the higher the work rate the smaller the fraction of total energy expense that goes for maintenance or for mere walking without a load. When the work-rate is very great, the overhead maintenance expense becomes negligible by comparison with total energy expense so that the *gross* and *net* costs per unit work become almost identical

⁹⁷ *Gross* energy cost includes resting maintenance; *net* energy cost does not include resting maintenance cost. *Absolute* energy costs does not include cost of walking without load. *Gross efficiency* is the ratio of work-energy accomplished to total energy expended; *net efficiency* is the ratio of work energy accomplished to energy expended above that at rest; *absolute efficiency* is the ratio of work energy accomplished to energy expended.

with *absolute* cost; that is, gross and net costs per unit work approach asymptotically the absolute cost. The analysis of the work data on the horses is compared with the results of thermodynamic theory (see also Chs. 2 and 3).

An analysis is presented of relative metabolism at various levels of effort and the influence of body size thereon. The ratio of maximal to minimal *oxygen consumption* is of the same order in horses and men, namely about 20; the ratio of maximal to minimal *energy expenditure* is of the same order in horses and men, namely about 100; the ratio of energy expenditure during sustained heavy work 8 hours a day, as encountered in daily life, to basal metabolism, is of the same order in horses and men, namely about 8.

Mechanisms limiting work capacity are discussed with special reference to blood circulation, pulmonary ventilation, oxygen-carrying capacity of blood, ability to incur oxygen debt, capacity of the coronary circulation, body-temperature regulation, nutritional and hormonal factors.

Methods of measuring work capacity are discussed critically with special reference to maximal oxygen consumption, maximum pulmonary ventilation, metabolic-adjustment rates. Special attention is given to oxygen consumption per heart beat per unit weight (oxygen pulse per unit weight) as index of work capacity.

The chapter closes with a brief discussion of the relative economy of horses and tractors followed by an appendix on tabular data, alignment charts, and supplementary charts.

24.8: Appendix.

24.8.1—Equations for energy cost of muscular work and for gross or overall energetic efficiency. If speed differences are disregarded, the relation of gross or overall energy expended, Q_o , to horse-power, H.P., is, for Horse 19,

$$Q_o = 1065 + 2339 \text{ H.P.} \quad (1)$$

If, however, the data are separated by speeds, then small but definite differences are found as shown by the following equations (upper half of Fig. 24.6a).

$$\begin{array}{l} \text{Liters oxygen per minute} \\ O_2 = 3.54 + 7.27 \text{ (H.P.)} \end{array} \quad \begin{array}{l} \text{Calories per hour} \\ Q_o = 1062 + 2181 \text{ H.P.} \end{array} \quad \text{Speed} = 1.15 \text{ m/hr} \quad (2)$$

$$O_2 = 4.03 + 7.47 \text{ (H.P.)} \quad Q_o = 1209 + 2241 \text{ H.P.} \quad \text{Speed} = 2.2 \text{ m/hr} \quad (3)$$

$$O_2 = 4.79 + 7.41 \text{ (H.P.)} \quad Q_o = 1437 + 2223 \text{ H.P.} \quad \text{Speed} = 3.1 \text{ m/hr} \quad (4)$$

The gross or overall efficiency, E_o , of the work may be computed from the above equations and from the equivalence of 1 H.P. and 642 Cal/hr (lower half of Fig. 24.6a).

$$E_o = \text{Gross or overall efficiency} = \frac{(\text{H.P.}) 642}{Q_o} \quad (5)$$

Substituting equations (1), (2), (3), and (4) in equation (5) separately, gives the equations for efficiency at speeds 1.15, 2.2, and 3.1 miles per hour. All these equations pass through zero-zero and approach asymptotically the maximum efficiency value.

Thus substituting eq. (1) in (5),

$$E_o = \frac{(\text{H.P.}) 642}{1065 + 2339 \text{ H.P.}} \times 100 \quad (6)$$

Dividing numerator and denominator by H.P.,

$$E_o = \frac{64200}{\frac{1065}{\text{H.P.}} + 2339} \quad (7)$$

The limiting value of efficiency becomes:

$$E_o = \frac{64200}{\frac{1065}{\alpha} + 2339} = \frac{64200}{2339} = 27.4\% \quad (8)$$

Fig. 24.17. Alignment chart for estimating horse power from draft (tractive pull) and speed. Thus to convert a 200-pound draft pulled at 2.5 miles per hour into horse-power stretch a string between 200 on the left scale and 2.5 on the middle scale and read the answer (1.33 horse-power) on right scale.

Similarly for equations (2), (3), and (4) the maximum efficiencies are:

$$29.4\% \text{ for speed } 1.15 \text{ mph} \quad (9)$$

$$28.6\% \text{ for speed } 2.2 \text{ mph} \quad (10)$$

$$28.8\% \text{ for speed } 3.1 \text{ mph} \quad (11)$$

These gross maximal efficiency values are evidently too high after we said that the maximal gross efficiency cannot exceed 25 per cent.

The problem of maximum efficiency may be approached from another point of view. The course of efficiency with increasing horse-power resembles the age curve of growth in weight represented by the equation $Y = A - Be^{-kx}$. This exponential equation was therefore fitted to the data by rectification on semi-log paper, as outlined in Ch. 16

Fig. 24.18. Alignment chart for estimating overall, or gross, energetic efficiency (on basis of 24-day maintenance) from body weight of horse and amount of work accomplished per day. Thus, if it is desirable to find the gross energetic efficiency of a 1000-pound horse working at the rate of 11 horse-power-hours per day, stretch a string between 1000 on left scale and 11 on the right scale and read the answer, 17.5 per cent, on the middle scale.

with the following results:

$$E_o = 25.0 (1 - e^{-1.79 \text{ H.P.}}) \quad \text{Speed} = 1.15 \text{ mph} \quad (12)$$

$$E_o = 24.5 (1 - e^{-1.41 \text{ H.P.}}) \quad \text{Speed} = 2.2 \text{ mph} \quad (13)$$

$$E_o = 24.0 (1 - e^{-1.20 \text{ H.P.}}) \quad \text{Speed} = 3.1 \text{ mph} \quad (14)$$

The resulting curves and the accuracy of the fit are shown in the lower half of Fig. 24.6a, and are entirely reasonable.

It may be noticed that equation (7) more nearly represents the data in the region from about 0 to 0.75 H.P. than equations (12), (13), and (14). On the other hand, (12), (13), and (14) more nearly represent the data from about 0.75 to 2 H.P. Above 2 H.P. there is little difference within the range of the data.

The exponential-equation method (12, 13, 14) appears to be better suited for relating the course of overall efficiency with increasing horse-power than the "rational" sub-

Fig. 24.19. Alignment chart for estimating feed (TDN requirements) from body weight of horse and work accomplished. To find TDN required by a 1250-pound horse working at the rate of 9 horse-power-hours per day, stretch a string between 1250 on left scale and 9 on right scale and read the answer, 21 pounds TDN, on the middle scale.

stitution method (6, 7, 9, 10, 11), first, because the substitution method is based on the assumption that the energy expense is a linear function of horse-power. This assumption probably does not hold for higher horse-powers (see Fig. 24.3). The exponential equation, on the other hand, is frankly empirical, used with the full understanding that efficiency goes through a maximum, after which it declines rapidly with increasing horse-power. In other words, there is an implicit limitation against the use of the exponential equation beyond a certain value. Moreover, the maxima overall efficiency values obtained by the exponential-equation method (24 per cent to 25 per cent) appear to be more reasonable than the maxima derived by the substitution method (28 per cent

Fig. 24.20. Alignment chart for estimating profit or loss on horse at given work price (10 cents per horse power), and given feed price (\$1.00 per 100 pounds TDN) from body weight of horse and work accomplished per day.

to .29 per cent). Finally, the exponential equation fits⁸⁸ the data better in the 1 H.P. region, which represents the "standard" power output of a horse.

Fig. 24.21. Photograph of our treadmill-metabolism apparatus (cf. Fig. 24.1).

⁸⁸ The irregularities of the data are due largely to the fact that they were secured at varying intervals, in one case 7-months apart, when the horses were in widely varying physical conditions and body weights. The 1500-pound horse worked on an outlying farm a considerable distance from the laboratory, and could rarely be spared for measurements; the pony likewise worked in a mine some distance away.

In connection with the discussion of relative reasonableness of 24 per cent to 25 per cent and 28 per cent to 29 per cent as gross efficiency maxima, it may be noted that the "absolute efficiency" (equation 3.3) is the theoretical maximal limit of gross and net efficiency. The absolute efficiency represented by the bottom curve of Fig. 1.4 (end of Ch. 1) is of the order of 30 per cent; therefore, gross and net, efficiency can never reach 30 per cent, but approach 30 per cent as a limit, 28 per cent to 29 per cent is too close to the maximum to be reasonable.

As regards the influence of the number of hours worked per day on efficiency and profit, all-day work efficiency is, of course, much below working-hour efficiency, and it varies with the number of working hours as illustrated in Fig. 24.10 and the following equations.

The equation for all-day efficiency, as function of hours worked per day may be derived from equation (1) and from the energy expended during standing. If N is number of hours worked, and 607 Cal are expended per hour while standing at rest,

Fig. 24.22. Photograph of the Kaiser-Wilhelm Institute for the physiology of work, Dortmund, Germany (1931).

then the all-day energy expended, Q_o , is

$$Q_o = (24 - N) 607 + N (1065 + 2339 \text{ H.P.}) \quad (15)$$

The calorie equivalent of the work accomplished is

$$Q_{wa} = 642 \times \text{H.P.} \times N \quad (16)$$

The gross or overall efficiency, E_o , is then,

$$E_o = \frac{Q_{wa}}{Q_o} = \frac{642 \text{ H.P.} \times N}{(24 - N) 607 + N (1065 + 2339 \text{ H.P.})} \quad (17)$$

This equation may be simplified by assuming the horse to work at the rate of one horse-power and collecting terms, giving,

$$E_o = \frac{642 N}{14570 + 2793 N},$$

which is the equation of the curve of Fig. 24.10c (right side).

The variation of profit with hours worked per day (left side of above Fig.) gives a different picture. We may assume the value of work accomplished to be 10¢ per horse-power-hour and the cost of the feed 1¢ per lb *TDN*. Since 1 horse-power-hour is equiva-

Fig. 24.23a. Photograph of our field-work-metabolism apparatus. The trailer on which the weight ergometer is mounted is pulled by the car at the desired speed and the mule pulls the given ergometer weight at the speed set by the car. The respiratory system of the animal is connected by a mask to gas meter and aliquoting apparatus within the car. This apparatus was built by James Sappington under the early direction of C. W. Winchester and later direction of H. H. Kibler, who will report in a joint monograph from the U. S. Dept. of Agriculture and the Univ. Missouri Agr. Exp. Sta. within the year on its details and experimental results obtained therewith.

Fig. 24.23b. Ergometer enlarged, indicating how the animal pulls on the weight in the ergometer.

lent to 642 Cal and 1 lb *TDN* to 1814 Cal, we have $\frac{.10}{642}$ dollar per Cal of work accomplished,* and $\frac{.01}{1814}$ dollar per Cal of energy expended. Thus, referring to equations 15 and 16, the equation for profit (the value of work accomplished minus the cost of feed required) may be written

$$\text{Profit} = \frac{.10}{642} Q_{ws} - \frac{.01}{1814} Q_o \quad (18)$$

$$= \left\{ \frac{.10}{642} \times 642 \times \text{H.P.} \times N \right\} - \left\{ \frac{.01}{1814} [(24 - N) 607 + N (1065 + 2339 \text{ H.P.})] \right\} \quad (19)$$

For a work rate of one-horse this equation reduces to

$$\text{Profit} = .10N - .01 \frac{14570 + 2793N}{1814} = -.0803 + .0846N \quad (20)$$

The above equation indicates that, unlike efficiency, profit is *linearly related* to the number of hours worked.

Fig. 24.23c. The connection of the animal's muzzle to the gas meter.

In brief, as shown in Fig. 24.10c, the increases in all-day efficiency (a ratio) with increasing number of hours worked per day decreases; but the increase in profit (a difference) per day is constant; that is, the profit increments per day per animal increase linearly with the number of hours worked per day, but the efficiency increment decreases exponentially with increasing work hours per day.

24.8.3: Alignment charts. Some of the above aspects may be represented as alignment charts or nomographs (for methods of construction see Univ. Missouri Agr. Res. Bull. 239, 1936).

Relation between load, speed, and horse power. Fig. 24.17 shows this relation. Thus, if it is desired to find the horse-power developed when a 200-lb draft is pulled at the rate of 2.5 miles an hour, a straight edge is placed (or a string is stretched) across the chart between points 200 on the draft scale and 2.5 on the speed scale, and the answer, 1.33 horse-power, is read on the horse-power scale. Draft values on scale A, of course, refer to horse-power values on scale A, and draft values on scale B refer to horse-power values on scale B. Similar technique is used in the other charts.

This nomograph was constructed from the relation

$$\text{H.P.} = D \times \frac{5280}{1980000} \times S = D \times 0.002667S \quad (21)$$

(D = draft or load in pounds; S = speed in miles per hour)
 Letting, $H.P. = Z$, $D = X$, and $.002667S = Y$, equation (15) becomes

$$Z = X \cdot Y \quad (22)$$

which, is the general equation of a Z type nomograph (Univ. Missouri Agr. Res. Bull. 239, 1936).

Fig. 24.23d. Gas meter within the car and the aliquoting sampling tubes.

Fig. 24.23e. Sideview of the interior of the car and its equipment.

Relation between body weight, work accomplished, and overall or gross efficiency. This is shown in Fig. 24.18. Example: A 1000-lb horse performing 100 horse-power-hours of work per day (24 hours) has an all-day (including resting time) mechanical efficiency of $17\frac{1}{2}$ per cent (answer obtained on efficiency scale by stretching string between 1000 on body-weight scale and 11 on horse-power-hour scale).

Fig. 24.18 is based on the *TDN* partition equation (Ch. 21).

$$TDN = 0.053M^{0.73} + 1.27 \text{ H.P.-hr} \quad (23)$$

in which the maintenance term is assumed equal to that found for cows (Ch. 21), $0.053M^{0.73}$. The work term, 1.27 H.P.-hr, is derived from the linear relation of Q_o to H.P. (equation 1 in which it is seen that 2300 Cal/hr are expended per H.P. above a constant for maintenance).

By definition, the gross or overall efficiency is

$$E_o = k \frac{\text{H.P.-hr}}{TDN} \% \quad (24)$$

where k is a factor for converting the work and feed to the same units, and multiplying by 100 for percentage. If *TDN* is expressed in pounds (1 lb *TDN* = 1814 Cal), $k = 35.34$. Substituting equation (23) in (24) gives,

$$E_o = \frac{35.34 \text{ H.P.-hr}}{.053M^{0.73} + 1.27 \text{ H.P.-hr}} \quad (25)$$

Taking the reciprocals

$$\frac{1}{E_o} = \frac{.053M^{0.73}}{35.34 \text{ H.P.-hr}} + \frac{1.27 \text{ H.P.-hr}}{35.34 \text{ H.P.-hr}} \quad (26)$$

or

$$\frac{1}{E_o} = \frac{.001500M^{0.73}}{\text{H.P.-hr}} + 0.03594 \quad (27)$$

Let $.001500M^{0.73} = X$, $\frac{1}{\text{H.P.-hr}} = Y$, and $\left(\frac{1}{E_o} - .03594\right) = Z$, then equation (27) becomes,

$$Z = X \cdot Y \quad (28)$$

which is the general equation of the Z type chart (Univ. Missouri Agr. Exp. Sta. Res. Bull. 239, 1936).

Feed standard: Feed (TDN) needs for different body weights and work rates. Fig. 24.19 represents the relation between body weight of horse, work accomplished per day (of 24 hours), and feed in the form of *TDN* required per day (of 24 hours). Thus a 1250-lb horse working at the rate of 9 horse-power-hours of work per day needs about 21 lb *TDN* per day. Fig. 24.19 is supplemented by Tables 24.3c and d.

Fig. 24.19 is merely an adaptation of equation (23) to an alignment chart. By letting $TDN = Z$, $0.053M^{0.73} = X$; and $1.27 \text{ H.P.-hr} = Y$, equation (23) may be rewritten

$$Z = X + Y \quad (29)$$

which is the general equation of the parallel line chart (Univ. Missouri Agr. Exp. Sta. Res. Bull. 239, 1936).

Profit for given work rates by horses of different body weight, represented in Fig. 24.20, was constructed on the assumption that feed for horses costs 1 cent per pound *TDN*, and work power sells at 10 cents per horse-power-hour. Work is estimated, with the aid of Fig. 24.17, from the load pulled and the speed with which it was pulled.

By profit we mean value of work less cost of feed. Assume the cost of feed to be \$1.00 per 100 lb TDN, and the value of the work done, 10 cents per horse-power-hour (\$1.00 per day for a 10 H.P.-hour day).

$$\text{Profit} = 0.10 \text{ H.P.-hr} - 0.01 \text{ TDN} \quad (30)$$

Substituting equation (23) in (30) gives,

$$\text{Profit} = 0.10 \text{ H.P.-hr} - 0.01 (.053M^{0.73} + 1.27 \text{ H.P.-hr}) \quad (31)$$

or

$$\text{Profit} = 0.0873 \text{ (H.P.-hr)} - 0.00053M^{0.73} \quad (32)$$

Let $(-0.00053M^{0.73}) = X$, $0.0873 \text{ H.P.-hr} = Y$, and $\text{Profit} = Z$, then equation (31) becomes

$$Z = X + Y \quad (33)$$

which is the general equation of the parallel line chart (Univ. Missouri Agr. Exp. Sta. Res. Bull. 239, 1936).

N = Number of data points represented in average.

$$M = \text{Mean} = \frac{\sum X}{N}$$

$$\sigma = \text{Standard deviation} = \sqrt{\frac{\sum X^2}{N} - (M_x)^2}$$

$$\text{P.E}_m = \text{Probable error of the mean} = \frac{.6745\sigma}{\sqrt{N-1}}$$

$$V (\%) = \text{Percent variation} = \frac{\sigma}{M} \times 100.$$

Table 24.3a. Energy and Hypothetical Monetary Expenses for a Typical 1500-pound Work Horse and a Typical Ignition Type Farm Tractor.

It is assumed that the horse pulls 150 pound draft at 2.5 mph, or works at the rate of 1 horse-power. The tractor works at 12 H.P. with a gross efficiency of 13.4%

Chapter 25

Summary and Integrating Discussion

25.1: Summary

Human beings possess a capacity which is entirely peculiar to them—the capacity to summarize the experience of the past. *Alfred Korzybski*

As indicated by the title of this book, our original material is on energy and nitrogen metabolism (Chs. 13–15) including some bioenergetic methods (Ch. 12), on energetic efficiency of productive processes (Chs. 3, and 21–24), and on various aspects of growth (Ch. 16), aging (Ch. 18) which we consider as inseparable from growth, on the interrelation between part and whole (Ch. 17) which we consider inseparable from the relation of energy metabolism to size (Chs. 13 to 15), and on physiological time and equivalence of age (Ch. 19).

Naturally, the factors influencing efficiency were analyzed, such as the influence of plane of nutrition (Chs. 4 and 5), metabolic catalysts, including enzymes, minerals, and vitamins (Ch. 6), hormones (Ch. 7), season (Ch. 8), time of day (Ch. 9), temperature (Ch. 11), and nutritional balance (Ch. 20). Likewise, the factors influencing profit were discussed with special reference to plane of nutrition (Ch. 5), body size (Ch. 22), productive plane (“dairy merit” in cattle, Ch. 22, muscular work in horses, Ch. 24, egg production, Ch. 23).

Many of the problems discussed have not yet been investigated. Such is the influence of the immediate efficiency and profit on longevity and fertility (long-range efficiency and profit). Is unusually rapid growth associated with early aging? Is hard muscular work associated with early aging? Is unusually high milk or egg production associated with early mortality or disability? These questions are difficult to answer categorically because in most cases the exceptionally high productive level under “average” conditions is the result of a sound body which normally favors longevity and fertility. If, however, the productive level of a given animal is accelerated by special methods, longevity and fertility may well be reduced. Thus accelerating winter egg production by artificial illumination increases the mortality rate; dairy cows may be “burned out” prematurely by forced high milk production; the hard working farm or mine horse does not live as long as the country gentleman’s carriage horse.

The theoretical feature of this book is the attempt to generalize large bodies of cumbersome data by simple rational but broadly inclusive equations. Thus the relative-growth equation, $Y = aX^b$, relating part, Y , to whole X (Ch. 17), or of energy and endogenous nitrogen catabolism, Y , to body weight X (Chs. 13 and 14), or maintenance cost Y to body weight X (Ch. 15), or milk or egg production, Y , to body weight X (Chs. 21–23), are based in one case (Ch. 17) on animals ranging from mice to whales, and in another (Ch. 13), from mice to elephants, thus giving the results general validity.

Similarly, the growth and aging equations $Y = Ae^{kt}$, $Y = Ae^{-kt}$, and $Y = A - Be^{-kt}$, relating body size, or population size, or aging, Y , to age or time t (Chs. 16–19) are applicable to species ranging from mice to large farm animals and to populations from bacteria to humans. Equivalence charts indicate species similarities and differences (Ch. 19) and point out the significance of the concept of physiologic time as contrasted to physical time (Ch. 19).

The above growth equation for the self-inhibiting phase (Sect. 16.5) also represents the principle of diminishing increments (Ch. 5), relating net energy produced (milk production, meat production, egg production, muscular work) to gross energy (feed) consumed (Figs. 1.1 to 1.3).

The theoretical analyses brought many bits of agriculturally useful information as, for example, how metabolism and maintenance costs vary with age and weight (Chs. 13–15); how pulmonary ventilation and water vaporization vary with weight and age (Ch. 14); how to measure the cardio-respiratory reserve for muscular work in animals ranging from mice to elephants (Ch. 24); how temperature influences productive processes (Ch. 11); how to evaluate the partition of feed consumed between maintenance, growth, milk production (Ch. 21) and egg production (Ch. 23); how the plane of nutrition influences the efficiency and profit on milk production (Chs. 5 and 22); how body size of cattle influences energetic efficiency and profit on milk production; the relative energetic efficiency of milk, egg, and meat production (Ch. 3). To elaborate on the last point, milk production is the most efficient of the three processes. Up to 50 per cent of the consumed *TDN* (total digestible nutrients) energy may be converted into milk (Chs. 3, 21, 22), twice as high as for the maximum possible efficiency of egg production (Ch. 23) and several times as high as for beef production (the efficiency of meat production is high, about 30%, shortly after birth but it declines rapidly thereafter with increasing age (Ch. 3). These are not arguments in favor of milk or against eggs or beef production, because the consumption of egg and beef is not on the basis of economy alone. If economic feeding were the only consideration, the method of India and China—feeding on whole cereals and vegetables—would be preferred; the second most economic method is that practiced in much of eastern Europe and in parts of Africa where whole cereals and milk (and cheese) are the staples.

Energetic efficiency of conversion is not the only consideration in the choice

of animals and animal products. Beef production may be from the technical energetic viewpoint wasteful, but practically economical because the beef may be produced largely on grazing, utilization of forage which would otherwise be wasted. The same is true of many other processes. Thus a horse may be less efficient energetically than a Diesel engine but the farmer does not have to pay for the horse fuel or for the horse; the forage grows on the farm and the horse reproduces and repairs himself.

The productive level is a very important aspect of the profitableness of an enterprise. While the maximum efficiency of milk production is 50 per cent, most "good" cows produce milk at an efficiency of only 25 per cent which just about pays for the dairyman's labor, feed, and other expenses. "Making money" in the dairy business involves greater efficiency of milk production. A 33 per cent efficiency indicates a "superior" dairy cow, and a profitable one (Ch. 22). But the profit is complicated by body size and related factors.

The size of the dairy cow is not a factor in the *energetic-efficiency* complex—rats, goats, small and large dairy cows and even women, tend to produce milk at the same *energetic* efficiency; but size (and related considerations) is an important factor in the *monetary-profit* complex. If the energetic efficiencies and other conditions are equal, the larger the animal the greater the milk return per unit human labor expended because it does not take much more time or labor to milk, feed, clean, rear, and manage a large than a small animal. Thus to produce 1000 lb of milk (of 4% fat) at 30 per cent energetic efficiency, it requires (Ch. 22) 26 of 1700-lb cows, or 30 of 1400-lb cows, or 38 of 1000-lb cows, or 42 of 900-lb cows, or 53 of 700-lb cows, or 200 of 100-lb goats; and it obviously takes more labor to milk, feed, etc., 200 goats than 53 cows, 53 cows than 38 cows, 38 than 26 cows, and so on.

25.2: Integrating discussion.

If we could first know where we are and whither we are tending, we could better judge what to do and how to do it. *Abe Lincoln*

The tower of Babel was a part of a plan to penetrate Heaven . . . magnificent . . . but it ended in confusion. *Willard H. Dow*

The progress in agricultural production is inseparable from the progress of science, and industry; and the 150-fold increase of the human population in the past 300 years in what we now call U. S. A. is a direct consequence of the progress in agricultural production. All our present social, economic, political, military and related problems are tied up with the growth of our population dependent on the progress of science, agriculture and industry. It may be useful to discuss some of these interrelations in summary fashion from the viewpoints of homeostatis and organismic theory (Ch. 10), growth (Ch. 16), and thermodynamics (Ch. 2).

It was shown in Chapter 10 on homeostasis that while the animal body is made up of a very unstable stuff (protoplasm), and while the sheer process of living produces incessantly substances—such as carbonic acid, sulfuric

acid, phosphoric acid, and related wastes—highly destructive to protoplasm, yet the body maintains a remarkably uniform “internal environment” and a stable pattern, in the case of man for perhaps a hundred years. The living body is evidently equipped with extremely efficient devices for maintaining constant its “physiological constants” despite many vicissitudes.

The concept of physiologic homeostasis in the individual organism was extended in Section 10.9 to include social homeostasis. This section is an extension of Section 10.9 on social homeostasis to agricultural developments and to the past, present, and future growth of the human population in the U. S. A.

The growth curve of the human population in the U. S. A. was discussed in detail in Section 16.8, and illustrated graphically in Figs. 16.56A to C. We now proceed from where we left off in Sections 10.9 and 16.8. In this connection Fig. 18.1a on the time changes in age distribution of the human population is also significant.

The human population in what is now called the U. S. A. numbered about 1 million at the time of Columbus' arrival (450 years ago) or the Pilgrims' arrival (300 years ago). From the principle of population growth (Sect. 16.5: the biotic power of an animal is limited only by the repressive forces in the environment) the population then numbered 1 million only because the environment would not permit a larger population. Our present population is about 133 million, and curve 1 in Fig. 16.56b shows that it will be about 160 million within 50 years, by the year 2000. Thompson's recent book,¹⁷ substantiates this prediction.

The rise of this population was evidently associated with the coming of Europeans. How did the coming of Europeans expand the population-supporting capacity 150-fold?

First, Europeans introduced new prime movers, the horse and ox. These freed man from much heavy physical labor, thereby enabling him to cultivate more land per man. Second, the Europeans stabilized food production by systematic cultivation, introducing improved domesticated plants and animals which need less land and time per unit food production than wild animals hunted by the Indian. It saves time to have the animals and plants in one place rather than to have to hunt for them.

The North American Indian had apparently only one domestic animal, the dog. The Indian also hunted the wild turkey, partridge, pigeon, goose, duck, deer, buffalo. The North American Indian had wild crabapples, cherries, grapes, strawberries, cranberries, gooseberries, huckleberries, raspberries, blackberries; he had cultivated maize (corn), beans, peanuts, potatoes (“Irish” and sweet), pumpkin, and some varieties of cotton. Europeans introduced horses, cattle, sheep, goats, domestic fowls; wheat, rye, barley, oats, peas, and most of the fruits; and improved the Indians' cultivated crops.¹

¹ South America had other animals and also plants such as tomatoes and peppers, and South America had a population of, perhaps, 8 million as contrasted to 1 million in North America.

The stupendous increase in the North American population is due, however, not so much to the introduction of European animals, plants, and knowledge as such, as to the European method and tradition of incessantly *creating new knowledge*—the invention of invention—and immediately applying it to the business of producing the things which ordinarily limit population growth—food, shelter, transportation, and communication. The period of rapid population expansion in North America is associated with what is called the Industrial Revolution (1770–1840) and with the wonderful nineteenth century of ever more rapid growth of machine technology and factory methods.

Beginning with the introduction of Arkwright and Cartwright's mechanical spinning and weaving methods, which revolutionized the textile industry between 1770 and 1780, there followed Eli Whitney's cotton gin (1793) for separating seed from cotton which made the United States a great exporting country and revived slavery; Fulton's steamboat (1807) lead to the development of the canals and the river cities, New Orleans, St. Louis, Cincinnati, Pittsburg; then the railroad:² in 1830 there was built the 11-mile Baltimore & Ohio along which chugged trains at a speed of 13 miles per hour. These 11 miles of 1830 grew to 30,000 miles by 1860. In the same period, 1830–1860, came John Deer's steel plow, McCormick's reaper and thresher, the grain drill, the grain elevator, mowing machine, the sewing machine, 2-horse straddle cultivator, the kerosene lamp (which crowded out the candle-making industry!).

In the next 30 years, 1870–1900, came the gang plow, silo, cream separator, combine harvester, the Babcock butter-fat tester (1890) which gave a new yardstick for evaluating dairy cattle. By 1900 came the automobile, tractor, airplane, electric power and electric communications. The horse is being replaced to a large extent by mechanical power at the expense of the "free" energy (Ch. 2) of petroleum stored in the past ages.

The perfection of the combine harvester is eliminating enormous numbers of farm hands; the mechanical cotton picker, not yet perfected but which undoubtedly soon will be, will eliminate hundreds of thousands of field hands, sharecroppers and small land owners; likewise as regards mechanical corn harvesters which pick and shell corn in one operation, forage harvesters, including side-delivery rakes and pick-up hay bales, and so on.

Such discoveries as chemical fertilizers, immune sera, antitoxins, insecticides, methods of control of infectious diseases, improvements of plants and animals by scientific breeding and artificial fertilization also eliminate human labor by increasing production, by making two blades of grass grow where one grew before. Thus hybrid corn increases the corn yield 20 per cent. It is said that a new hybrid corn is growing in a Mississippi locality at the rate of 130 bushels an acre, whereas, because of unfavorable temperature, ordinary corn produced only 20 bushels an acre.

The sum total is that ever more is produced by fewer farmers. In 1830, 50 to 60 man-hours were required to produce 20 bushels wheat from an acre; in 1925, 3 to 4 man-hours were required to produce 20 bushels of wheat from an acre.

Mechanization of urban industries has grown even more rapidly than that of agricultural production.

² The steam engine was invented by James Watt (Glasgow) in 1785. The first English locomotive was made in 1804 and the first English railway was run in 1825. The first steamboat was run in England in 1802. The first steamship crossed the Atlantic in 1819.

These developments indicate the unique power of knowledge, especially the European tradition of accumulation of new knowledge and its application, and especially what Charles Kettering calls the capacity or experience of change-making. Science and technology is a continuously changing process. This new knowledge enabled the human population to increase some hundred-and-fifty fold above the original Indian population.

However, the percentage increase in population in the United States has been subsiding since 1880 (Fig. 16.56a and c). Thus the population gain during 1920-1930 was 17 million, whereas the gain between 1930-1940 was only 8 million, and it is rapidly approaching a ceiling (Fig. 16.56b). Why is the growth rate of our population declining? It is not due to the lack of food or other consumers' goods. Indeed, the apparent market surpluses (prior to the present war) are embarrassing in their magnitudes. Nor is it due to lack of "living space" because the population density in the U. S. A. is only about 40 persons per square mile (as contrasted, for example, to 670 in England and Wales, 665 in Belgium, 562 in Netherland, 347 in Germany, 340 in Italy, 320 in Japan, and so on).

Life in the U. S. A. is theoretically and could be actually extremely pleasant. Medical progress is freeing us from epidemic diseases, communication progress is giving us unlimited opportunity for social contacts, mechanical progress is freeing us from heavy labor, agricultural and nutritional progress is freeing us from malnutrition. Why, then, is the percentage increase in population declining?

The principle of homeostasis (Ch. 10) appears to substantiate the old suggestion that perhaps "everything seems pregnant with its contrary." Thus the development of ever better farm machinery, of course good in itself, displaces many farm workers. It is estimated that since 1787 the productivity per farmer (or mechanized farms) increased 60-fold (after deducting the time required to make the farm machinery); during the year 1935, about 345,000 farm workers were displaced on American farms by farm machinery and perhaps as result a million-odd farm families were receiving (1938) relief assistance. The relative decline in rural population, indicated by the following data, may be attributed to agricultural progress, to our ability to produce more food with fewer farm producers.

The decline in the number of agricultural producers is greater than is indicated by the following table. Of this rural population, perhaps only 20 per cent (rather than the indicated 43 per cent) is now employed in productive agriculture as contrasted to about 95 per cent in 1790. "Fifty per cent of all American farms produce only 10 per cent of our commercial farm products. More than a million and a half men and boys of working age who lived on farms in 1937 registered as partly or wholly unemployed" (H. R. Tolley).

This movement from the farm to city lead to repression in population growth because wife and children were economic assets on the farm but are liabilities in the city. When, in addition, living and especially educational standards

Relative Growth of Rural Populations³ in the U. S. A.

Year	Total population (millions)	Rural population (millions)	Percentage rural popula- tion
1790	3.9	3.7	95
1800	5.3	5.0	94
1810	7.2	6.7	93
1820	9.6	8.9	93
1830	12.9	11.7	91
1840	17.1	15.2	89
1850	23.2	19.6	85
1860	31.4	25.2	80
1870	38.6	28.7	74
1880	50	36	72
1890	63	41	65
1900	76	46	60
1910	92	50	54
1920	106	52	49
1930	123	54	44
1940	132	57	43

are high, children become serious economic burdens with resultant delay in parenthood and therefore in birth-rate (Sect. 16.8). This movement from farm to city may, then, be the basic cause of declining birth rate, although subsidiary causes, such as changing attitudes to birth control may be important contributing factors.

Urban populations likewise tend to suffer from technological unemployment. Thus⁴ while the electric-lamp production index *increased* from 100 in 1920 to 139 in 1930, the hours required to make the lamps *decreased* from 100 in 1920 to 32 in 1930.

War may be the blind social homeostatic mechanism for relieving unemployment in a society which cannot invent better methods for maintaining constant its "internal environment." The biology of war and the involved compensating homeostatic mechanisms have been discussed in Section 10.9 where it was pointed out that, among other factors, the greatest immediate need is development of methods for selecting leaders who will utilize the tools of science, which grow ever more powerful, for peaceful construction rather than for warlike destruction. This is by no means a new idea.⁵

In closing it may be useful to discuss the significance of the accelerated

agricultural and industrial production in the light of the laws of thermodynamics (Ch. 2), to view the bioenergetic situation as a whole.

According to the second law of thermodynamics, our prodigious increase in population and mechanization must be paid for by increase in free energy expenditure.

Our two energy sources are: A) non-renewable, gas, gasoline and other petroleum products, and coal; B) renewable, products of the farm, forest and stream, and hydroelectric energy. Let us discuss each briefly.

A. *Non-renewable energy sources.*—With relatively few exceptions, our machines—including our 30 million peace-time automobiles—are powered, directly or indirectly, by petroleum and coal energy. Such processes as iron manufacture and, of course, transportation, involve the consumption of enormous amounts of gas, oil, and coal. These energy forms are vegetable remains of the geologic past, fossil fuels not renewable under present conditions. While, therefore, the rise in the curve of energy consumption is usually considered as the best index of enrichment it is thermodynamically the best index of free-energy impoverishment.

At the present rate of consumption, the *known liquid* fuel reserves are estimated to last 20 years. There is also oil remaining to be discovered. The discovery of sufficient liquid fuel to last another 50 or 100 years or even several hundred years does not change the overall picture that we are approaching the end of the “free-energy” oil era. We are in a much better position with regards to low-grade coal reserves. The following statement of our energy resources is given by the National Resources Committee.⁶

Our coal resources have been estimated (1937) at approximately 3000 billion tons, of which about half a billion tons is consumed annually. Our proven oil reserves have been estimated at 15 billion barrels of which about $1\frac{1}{4}$ billion barrels are consumed per year (during 1937). Our natural gas resources have been estimated at 60 to 100 trillion cubic feet (energy equivalent of about 17 billion barrels of petroleum), of which 2 trillion cubic feet are consumed per year (1937).

It is estimated that energy consumption per capita in the United States is 50 per cent higher than in Great Britain, over 200 per cent higher than in Germany, over 1000 per cent over that in Japan, and over 1500 per cent over than in China. From 1889 to 1929 each year's energy consumption increased 60 per cent above that in the preceding year. Of this energy (in 1937), 48 per cent was derived from bituminous coal, 6 per cent anthracite coal, 32 per cent petroleum, 10 per cent natural gas, less than 4 per cent water power. The United States has produced about 60 per cent of all the petroleum consumed in the world, as indicated in the following table.

⁶ Energy resources and national policy. National Resources Committee, U. S. Government Printing Office, Washington, D. C., 1939. The ordinary peace-time annual per capita petroleum consumption is 450 gallon in the United States, 80 gallon in the United Kingdom, 50 gallon in the U.S.S.R. The rate of per capita petroleum consumption in the United States is 30 times that of the rest of the world. The petroleum consumption in the United States provides the work equivalent to 140 servants per family.

Oil Production,⁷ 1940

	Million barrels per year	Percentage of world's production
United States	1406	63
Venezuela	223	10
Mexico	42	2

Central and South America	305	13
Europe	296	13
Asia	113	5
Oceania	72	3
Total World production	2251	100

Outside of the renewable vegetation energy, the most important is hydroelectric energy. The outstanding United States hydroelectric projects are the Grand Coulee and Bonneville Dams on the Columbia River, the Boulder Dam in Colorado, the Norris, Hiawassee, and Hales Bar Dams on the Tennessee River and its tributaries, the Keokuk Dam across the Mississippi River, the Fort Peck Dam on the Missouri River in Montana, the Shasta Dam on the Sacramento River in Northern California, and the Niagara-Hudson hydroelectric power plants.

A hydroelectric project now under consideration is the St. Lawrence-Niagara Development, in connection with the Great Lakes-St. Lawrence Seaway project. It is proposed to harness the flow of the St. Lawrence River at Massena, New York, and Cornwall, Ontario, to yield $2\frac{1}{2}$ million horse power and to improve the existing Niagara Falls facilities to yield another $\frac{3}{4}$ million horse power. This power output is expected to give "a new lease on life to New York State industries, a source of cheap electricity which should make possible the resumption of manufacturing growth."⁸ This power is said to be needed especially by electro-process industries, such as manufacture aluminum, ferro-alloys, carbides, dyes and other chemicals. Moreover, $\frac{3}{4}$ million horse power could be carried as far as New York City. The cost of the project ($1\frac{1}{2}$ billion dollars) would quickly pay for itself.

An attempt was made to utilize the water power from tides, especially in Maine (the Passamaquoddy Project), and one or two tide power plants are said to be in operation in Europe. This is a promising future source of renewable power.

Windmills are used, but the energy generated is relatively insignificant.

It has been suggested that temperature differences in the oceans, direct solar heat, and interatomic energy may be eventually utilized as sources of power. However, no

⁷ Egloff, G., *Chem. & Eng. News*, **20**, 649 (1942).

⁸ St. Lawrence Survey, U. S. Dept. Commerce.

substantial progress has thus far been made on these methods, and there are no encouraging signs that such will be made in the near future.⁹

B. Renewable energy sources.—It is said that we shall use alcohol and vegetable oils after the petroleum energy has been exhausted. This reminds one of Marie Antoinette's advice to the Paris poor to eat cake when they had no bread. Alcohol¹⁰ and vegetable oils are, of course, more expensive than petroleum fuels. Moreover, if all our crops were converted to alcohol and oil, they would not supply the present rate of petroleum-energy consumption.^{10a}

Furthermore, it appears that in spite of, or rather because of, the accelerated rate of agricultural production per man-hour of work, the agricultural productivity *per acre* is declining. Today, a man operating a tractor drawing a battery of plows can plow a hundred times the acreage he could a century ago with a walking plow; and there is a corresponding accelerated rate of soil erosion and removal of plant nutrients. The natural rate of soil formation is not equal to the rapid rate of soil and plant-nutrient removal by these mechanized methods. The mechanically-plowed ground loses as much of its soil in ten years as pasture in a 100 years.

There is, of course, disagreement among specialists concerning the cause and fate of declining soil fertility. To Whitney,¹¹ "the future seems most hopeful, the soil seems to be awaiting our pleasure." "The Chinese raise more per acre than is raised in the United States." One might cite other lands with a permanently high fertility. The conditions in the other countries are, however, different. The American farm crops are shipped to the cities, whence they find their way into the sewers, rivers, oceans and incinerators; the Chinese saves every bit of organic matter, and carries the "night soil" from the city to the farm. Furthermore, much of the permanency of fertility of certain regions of China is due to the recurrent fertility additions by fertile river mud. Similarly, the permanent fertility of the Nile Valley is due to the annual fertilization of the land by the Nile River.

Unlike Whitney, Bennet¹² is very pessimistic about American soil fertility, as indicated by the following quotation.

⁹ Hottel, H. C., *Sigma Xi Quarterly*, 29, 49 (1941). "The solar power is not there for the taking! With respect to the future of solar energy utilization, your guess is as good as mine."

¹⁰ cf. Shepherd, G., "Power alcohol from farm products." *Contrib. Iowa Corn Res. Inst.*, 1, 283 (1940): with corn at 50 cents per bushel, alcohol may be made for fuel blending purposes at 25 cents per gallon. If, however, we were to rely on alcohol as exclusive source of power for automobiles, the price of corn and alcohol would become very high indeed.

^{10a} For a more optimistic view, see Berl, E., "Production of oil from plant material," *Science*, 99, 309 (1944).

¹¹ Whitney, Milton, "Soil and civilization," New York, pp. 270, 272, 1925.

¹² Bennet, H. H., "Soil erosion and its prevention." Parkins, A. C. and Whitaker, J. R., Ed., "Our national resources and their conservation." New York, 1926. See also Bennet, U. S. Yearbook of Agriculture, p. 429, 1940, and U. S. Yearbook of Agriculture, 1938. See also, Duley, F. L., and Miller, M. F., "Erosion and surface-run off under different conditions." Univ. Mo. Agr. Exp. Sta. Res. Bull., 63, 1923.

Actual soil losses, as determined by exact measurements, are staggering. Approximately 50 million acres of once productive land has been ruined for crop use, and another 50 million acres is in almost as bad condition. Had it been protected, this aggregate 100 million acres divided into 80 acre farms would support 1,250,000 rural families.

Something over 100 million additional acres, largely still in cultivation, has lost all or the greater part of its productive topsoil; on yet other millions of acres erosion is getting actively under way. About 470 million acres lost from $\frac{1}{2}$ to $\frac{3}{4}$ of the top soil.

In addition to erosion losses, there are serious losses by cropping, grazing, and leaching. The latest estimates indicate the annual losses from these causes at approximately 1 $\frac{1}{2}$ million tons of phosphorus, 13 million tons nitrogen, 18 million tons potassium, 253 million tons organic matter.

The situation is even more discouraging to Stuart Chase, not a soil specialist but a very penetrating lay observer:¹³

Before the coming of the machine, farm wastes and manures returned minerals to the soil at about the same rate as they were taken out. But under the deep, one-crop, commercial farming conditions, minerals go out of the soil to the cities and they never come back.

A dust desert is forming east of the Rockies where firm grass once stood. The natural grass cover has been torn to ribbons by steel plows and cattle and sheep hoofs. Thousands of years of soil accumulation is lost in a century. Spindling woodlands cover only half the area the primeval forest once covered. Corn yields in sections of Iowa dropped from 50 to 25 bushels per acre. Half of the original fertility of the continent has been dissipated. American has achieved its high standards by living on its reserve capital, by taking more out of the continent than was put back.

There are historical parallels to our dust-bowl, dust-storm, migratory-worker problem in parts of Texas, Wyoming, eastern Colorado, western Kansas, and western Oklahoma. Thus, again from Chase:

There were 400,000 people in the city of Antioch; the pleasure gardens of Daphne were famous throughout the Mediterranean world. Today it is a miserable dusty town of 30,000. Antioch perished not from its sins but from erosion on the Taurus and Lebanon rivers.

One might cite other thoughtful observers, especially on historical parallels to our situation. Thus from Sears:¹⁴

The course of farm life and farm management in Rome ran from yeomanry to tenantry, and finally to holdings of absentee landlords. In spite of the exceedingly fertile lands of northern Italy, watered and nourished from the Alps, Rome entered upon a period of agricultural decline and could not feed her own people.

The following is from our former Secretary of Agriculture, H. A. Wallace:

We overplow the cropland, overgraze the pasture land, overcut the timberland, plow fertility into cities, which in time pours down the sewers into the river and the ocean.

¹³ Chase, S., "Rich land poor land." McGraw Hill Book Co., pp. 20, 21, 34, 36, 37, 342.

¹⁴ Sears, P. B., "Deserts on the march." University of Oklahoma Press, 1935.

It is true that: there is at present an apparent abundance of food; we can manufacture nitrogen fertilizers from the air; we can enrich soil with organic matter from nitrogen-rich legumes. Nevertheless, our machine-methods of cultivation will yield ever smaller crops in some regions, and in a few years, with the increased population living at a high standard, we shall need our land for food production, and it will not be possible to spare it for producing fuels as substitute for petroleum products and coal. We shall do well enough if we can supply food at a high standard to a population almost 200-fold that supported under the conditions of the American Indian 300 years ago. The decline in soil fertility, moreover, tends to reduce, or unbalance, the nutritive value of the crops that can be produced (see Sect. 20.8).

In brief, the phenomenal industrialization in the past century is based in part on borrowed capital and, one might say, borrowed time; capital and time accumulated in the past geologic ages. This capital is of two kinds: 1) petroleum fuel which is being rapidly exhausted, will perhaps be unavailable for ordinary use of private automobiles and tractors within a relatively short interval and coal which will last for a considerable period 2) soil which has also been severely exploited; but much of which, with proper care, will yield renewable vegetation energy perhaps indefinitely. A new source of permanent power is being harnessed productively, namely that of running water for generation of electricity. The other suggested power sources, such as conversion of solar energy to utilizable heat or electricity, or interatomic energy, are not promising.

This energetic viewpoint may be too pessimistic. We may find new energy sources. We may rebuild our soil losses and maintain our soil resources by turning our attention and imagination to the building up of the countryside instead of the cities.¹⁵ Such a new optimistic development is exemplified by the TVA (Tennessee Valley Authority), indicated by the following quotations from former U. S. Senator George W. Norris.¹⁶

Before the TVA, our fertile valleys were being depleted of their soil. . . . Annual floods swept through them at terrible cost. . . . Erosion was unchecked . . . and the swollen rivers carried . . . top soil down to the sea. The dams built by the TVA prevented flood damage, and also kept open navigable channels. A comparatively small additional sum enabled the Authority to utilize the waters impounded behind the great dams for the generation of huge amounts of electric power. This power has been carried into the homes of farmers and provided amenities they never knew before; it furnished cheap electricity to city dwellers; and in factories and industrial plants in the South it is contributing mightily to the war effort and bringing prosperity to the people.

¹⁵ Hammar, C. H., "Society and conservation," *J. Farm Economics*, **24**, 109 (1942).

¹⁶ Norris, George W., *The Nation*, May 20, p. 589, 1944, who also reviews W. C. Lowdermilk's recent book "Palestine: land of promise." Harpers, 1944. The author is Assistant Chief of the U. S. Soil Conservation Service, sent by the U. S. Department of Agriculture to study denudation and conservation of soil, especially in the Near East.

Then Norris quotes the suggestion for adoption of the TVA plan for the establishment of a JVA (Jordan Valley Authority) for reclamation purposes as follows:

Centuries ago Palestine was a prosperous country, covered with fertile fields of forests. Its fertility was destroyed by man's failure to conserve its natural resources. After Palestine was set aside as a Jewish homeland, it became a great experiment in reclamation. The Jews built cities and formed agricultural colonies and brought the soil back to abundant production. "It is practically impossible," says Dr. Lowdermilk,¹⁶ "to estimate what the final absorption capacity of Greater Palestine could be if all its unoccupied and underpopulated areas were rejuvenated by the same vigor and understanding. . . ." Once the undeveloped resources (hydroelectric power developed from the rushing river down the Dead Sea, reforestation, mineral extraction) of the countries are properly exploited, twenty to thirty million people may live decent lives where a few million now struggle for a bare existence. The principle of the greatest good for the greatest number and the principle of preserving the natural resources of the country should lead to ever wider adoption of the TVA principle, yes, even to developing a "TVA of the Danube," without regard to national boundaries, which would transform the economically backward Danube basin (Poland, Czechoslovakia, Austria, Hungary, Rumania, Yugoslavia, Bulgaria and Greece) into a prosperous one.

Senator Norris, however, presented only one aspect of the picture of the beneficent changes developed by modern science and technology. There is another aspect. According to the principle of population growth (Sect. 16.5), doubling the food supply merely doubles the population density without necessarily increasing its welfare. It has been predicted¹⁷ that (because of developing science and technology and perhaps for military reasons) the U.S.S.R. will grow from the present 174 million to 251 million by 1975; India may grow from the present 389 million to 500; China from the present 400 million to 600 million. . . . "The fulfillment of the most sanguine hopes of science and industry for increasing the means of living will be inadequate if birth control does not become the rule in all the world."¹⁷ Wars, however, "shake the biologic foundations of human life" and upset all predictions.¹⁸

25.3: Summary of summary.

The analysis of the whole, as a whole, is as necessary as the analysis of parts. *R. S. Lynd*

We suffer less from a want of science and technology than from lack of understanding of the aims of life and of society. *R. W. Hutchins*

We are on the threshold of a new era. But what sort of an era? *Quo Tai Chi*

This book has been preoccupied with the quantitative aspects of energy and nitrogen metabolism, with nutrition, with various phases of growth, development and aging, with the catalysis of these processes, with the energetic efficiencies and profits on milk, meat, eggs, and muscular-work production, with generalizing equations—so-called laws—for integrating unwieldy bodies of data.

During this writing a need was felt for a generalizing or unifying principle,

¹⁷ Thompson, W. C., "Plenty of people," Jacques Cattell Press, 1944.

¹⁸ Birth rates in warring countries," Editorial, *Jour. Am. Med. Assn.*, 125, 278 (1944).

perhaps comparable to the principle of evolution, perhaps some broadly organismic theory or conceptual scheme which would show by a word or phrase the interrelatedness of all the components of the field that we have been considering.

The ancient,¹⁹ perhaps vaguely felt, concept of physiological regulation ("The organism acts as though it desired to maintain itself" C. Sherrington) scientifically investigated since about 1860 (Claude Bernard), and recently designated homeostasis by Cannon (Sect. 10.11), comes nearest to meeting the need of a broadly unifying principle if its meaning is extended to include social self-regulation, including that of human society (Sect. 10.9). Senescence, disease, individual and social catastrophe, are due to or characterized by failure of homeostasis. Under condition of failing social homeostasis, subhuman animals are doomed. The sabretoothed tiger had to disappear because it developed his magnificent sabre-teeth weapons which tempted him to war-like action. On a human level, however, we may, perhaps, discover methods for preventing catastrophe in the face of our splendid weapons which tempt us to destructive wars, and our wonderful machines which consume our stockpile of "free energy" and our soil resources at ever greater rates.

The current confusions and maladjustments may be transitory, temporary disharmonies associated with rapid growth, in the nature of "growing pains," which may be resolved into a harmonious unity. But this is not certain. The future trends of human behavior are not predictable²⁰ because human behavior is modifiable by intelligence, by education, by laws of human making in contrast to the immutable natural laws which govern the social trends of subhuman populations. This relative indeterminacy of human behavior and social phenomena is the despair of the social scientist and perhaps the hope of humanity; for this gives man an opportunity to mold his destiny that is not given to other species that are subject to more determinate, orderly, laws. There is more than poetic significance to the biblical assertion that "The Kingdom of Heaven is within you." The major contemporary problem is how to employ science for guiding individual and social development so as to realize this Kingdom of Heaven on earth²¹.

Subject Index

A

- acclimatization and heat production, 283, 285-88
- acetylcholine, 128, 141
- acid-level regulation, 250-52
- acrodynia, 121
- acromegaly, 195, 201
- "active mass" as reference base, 363
- Addison's disease, 184-85
- adenyl pyrophosphate, 103-04, 134
- adrenal cortex, 184-88
 - and adrenal medulla, 184
 - and androgenic tissue, 187
 - and carbohydrate metabolism, 192
 - diseases of, 184-85
 - and related endocrines, 187
 - enlargement of, 186
 - and feminism in man, 186
 - functions of, 185
 - and glutathione, 187
 - and gonadectomy, 186-87
 - growth of, 185-86
 - hormones of, 150, 184-85
 - and the "infant Hercules", 186
 - and lactation hormones, 187
 - and the pituitary, 187
 - and salt metabolism, 185
 - and sex hormones, 186
 - and virilism, 186
- adrenalectomy, 187
- adrenal glands, 141, 185
 - and body weight, 586, 588, 591
- adrenaline, 184, 179-80
- adrenal medulla, 179-81, 184
- adrenosterone, 180
- age
 - and cancer incidence, 145
- changes
 - in form, 575-663
 - in homeothermy, 270-4, 276
 - in metabolism, 404-09
 - in pulmonary ventilation, 404-09
- curves of linear growth, 521-22, 554-63, 577-80, 598-617, 629-39, 650-63, 732-33, 737-38
- distribution of population, 665
- and efficiency of growth, 49, 53
- equivalence, 712-40
 - of man and other species, 492, 540-43, 715, 716, 720-22, 738-39
 - method of computing, 722-38
 - post-pubertal, 712-40
 - pre-pubertal, 720, 736-37
- and maintenance cost, 49
- aging, 664-711
 - of bacterial populations, 666
 - and blood pressure, 710
 - aging, causes of, 664-69, 674
 - and the circulatory system, 690
 - colloidal theory of, 673, 678-80
 - control of, 676-81
 - criteria, 698
 - and diet, 689-98
 - and digestive enzyme activity, 666
 - disease incidence in, 696-97
 - egg production as index of, 675, 700-2, 710-11
 - equations, 701-4
 - and exercise, 682-84
 - and eye accommodation, 668
 - and growth, 664-711
 - and homeostasis, 667, 699-700
 - indices and quantitative analysis of, 698, 706, 712-13
 - metabolism as index of, 667, 669-72, 674-76, 679, 685, 707-9
 - milk production as index of, 679-83, 686-95, 700, 702-5, 711
 - and neuroendocrine activity, 685-89
 - and reaction time, 667-700
 - reserve power as index of, 667, 699-700
 - and temperature, 684-85
 - theories, 668-75
 - wound healing as index of, 675
 - and vitamins needs, 764
- agricultural progress and population growth, 961-63
- air
 - alveolar, 919
 - analysis, 338-43
 - composition, 340
 - conditioning, 265, 302
 - expired, 340-42
 - inspired, 340
 - residual, 919
 - supplemental, 919
 - tidal, 919
- alcoholism and thiamine deficiency, 122
- "alkali disease", 101
- alkaline reserve, 921
- allometry, 609
- alopecia, 132
- altitude
 - and atmospheric pressure, 251
 - and hemoglobin concentration, 251
- altruistic drives, 257
- alveolar air, 919
- amino acids
 - biological oxidation of, 309
 - and biological value of protein, 760-1, 779
 - content in proteins, 776
 - content in typical foods, 776
 - deamination and oxidation of, 64, 309, 778
 - essential or indispensable, 741, 761, 776
 - formulas and functions of, 777

- amino acids, in nutrition, 741-44, 762, 774-80
 R.Q. of, 810
 and SDA, 778
p-aminobenzoic acid, 117, 127, 133, 142
 amniotic fluid, 437
 anabolism and catabolism, 129
 analysis of experimental data, 260-62
 androgens, excretion of, 149-50, 155, 159
 androsterone, 150
 anemia (see blood)
 dietary, 101, 115, 133-34, 181-83
 hypochromic, 115
 pernicious, 134, 782
 angina pectoris, 100
 anorexia, 101
 anoxia, 251
 anti-alopecia, 127
 anti-dermatitis, 127
 "anti-gray hair" vitamin, 134
 anti-hormones, 142
 anti-hormone (goitrogenic) drugs, 144
 anti-pellagra vitamins (see nicotinic acid)
 anti-rachitic value of milk, 802
 anti-vitamin drugs, 117, 142-43
 appetite
 definition of, 247
 as guide to "nutritional wisdom", 253-54
 and hunger, 247
 in relation to vitamins, 101
 ariboflavinosis, 132
 ascorbic acid (vitamin C)
 assay of, 767
 content in food, 769, 788-91
 as detoxicant, 121-22, 134, 138-39
 forms of, 120
 formula of, 117, 134
 and glutathione, 120, 137
 in hay fever, 122
 loss in sweat, 301
 maintenance need for, 475
 need for, in aging cattle, 110, 120
 need for, species and age differences in, 120-21
 oxidase, 115
 and scurvy, 134, 763
 synthesis and destruction of, 120
 and thyroid function of, 122, 178
 relation to vitamin A, 742
 auxins, 204-5
 avidin and biotin, 122
- ## B
- bacteria
 aging of, 666
 growth of, 499-500
 growth efficiency of, 40-41
 beef production
 efficiency of, 51-52, 790, 793
 statistics on, 790-91, 793-94
 Bernard, principle of, 243, 244
 betaine, 128
 biocalorimetry, 307-51
 computation methods in, 311, 328-9, 331, 334, 340-42
 direct methods, 307-8
 biocalorimetry, direct methods, compensation, 308
 differential, 308
 ice, 307
 water, 308
 of food, 35-36, 344
 history, 344-47
 indirect methods, 308-13
 closed-circuit chamber, 319, 325-29
 closed-circuit spiropographic mask, 313, 319, 330
 insensible perspiration, 290-92
 miscellaneous, 345-47
 open-circuit mask, 335, 338
 open-circuit gravimetric, 329-35
 partitional, 292-93
 principles, 307
 bioenergetics
 definitions, 12, 34
 symbols, 34
 and thermodynamics, 12-36
 units and equivalents, 23-36
 biologic oxidation
 aerobic and anaerobic, 102-4
 and aging, 101
 of amino acids, 64, 309, 778
 and angina pectoris, 100
 and anorexia, 101
 calcium in, 115
 of carbohydrates, 308
 cobalt in, 112, 115
 copper in, 101, 113, 115
 creatine in, 104
 cytochrome oxidases in, 107
 cytochromes in, 107
 decarboxylases in, 108
 definition of, 131
 dehydrogenase activity in, 105
 dehydrogenases in, 108
 "dissecting out" metabolic stages in, 105
 efficiency of, 100-1
 and electromotive series, 106
 electron losses in, 105
 energy reservoirs in, 104
 equations, 308
 of fat, 309
 flavoprotein enzymes in, 101, 107
 glycogen in, 104, 107
 H-acceptors in, 107
 hemocyanin in, 113
 hemoglobin in, 113
 H-transport systems in, 107
 indicators, 107
 interrelations between minerals, vitamins, and
 enzymes in, 109
 and intoxication, 101
 iodine in, 115
 iron in, 112-14
 iron-porphyrine enzymes in, 107
 lactic and phosphoric acids in, 103
 magnesium in, 112
 manganese in, 112
 methods of, 102-3
 minerals in, 101, 105, 111-16
 nutrients in, 107
 oxidases in, 108
 oxidation-reduction potentials in, 104-9

- biologic oxidation, and oxygen debt, 103
 - Rastear effect in, 103
 - phosphate in, 107, 111-12
 - phosphocreatine, adenosine, and pyrophosphate in, 103
 - phosphorylases in, 108
 - phosphorylation in, 107-8, 111, 132
 - poisons or inhibitors in, 104
 - of protein, 309
 - pyridino-protein enzymes in, 107
 - of pyruvic acid, 100
 - respiration and fermentation in, 102-3
 - riboflavin in, 101
 - effect of selenium on, 101
 - stepwise processes in, 100, 107, 131
 - thiamine in, 100
 - timing of, 100-1
 - vitamins in, 101, 116-28
 - sine in, 115
- biologic value of protein, 742, 760-61, 778-80
- bios, 118, 132
- biosynthesis, 484
 - in alimentary tract
 - of non-ruminants, 742-43
 - of ruminants, 741-44, 762
 - of amino acids, 129-31, 741-43
 - of vitamins, 741-43
- biotin (vitamin H; coenzyme R), 125-26, 133
 - and avidin, 122
 - deficiency of, 133
 - formula of, 117, 126
 - functions of, 126
 - and perosis, 126
 - procarcinogenic effect of, 126
- birth
 - rate, factors in decline of, 965
 - weight and gestation, 427-42, 460
- Bittner factor, 145, 700
- "blackouts", 928
- blastocyst, 491-92
- blood, 101, 112-13, 115, 133-34, 921-22
 - influence of altitude on, 922
 - CO₂ removal from, 113
 - hemoglobin in, 113, 251, 922
 - intensity and capacity factors of, 922
 - lactate in, 930
 - O₂ and CO₂ in, 251
 - pH regulation in, 244, 252
 - pressure and aging, 710
 - regenerating values of foods, 781-83
 - sugar regulation, 248-49
 - volume and fetal weight, 428
 - weight, 593
- body build, 587-90
- body size (see weight)
- body temperature, 293
 - regulation during work, 924
- body-water regulation, 248
- body-weight (see weight)
- bomb calorimetry, 344
- brain metabolism, 407-9
- brain weight
 - evolutionary significance of, 255-56
 - and heat production, 619-24

- brain weight, and body weight, 592, 626
- butter-margarine controversy, 800
- digestibility, 800
- fatty acids in, 800-1
- effects of growth, 795, 799-800
- supplementary values, 799-800
- vitamin A in, 801

C

- calciferol (vitamin D₂), 135, 143
- calcium
 - amount in body, 116, 189
 - in biologic oxidation, 115, 137, 781
 - in foods, 787-91
 - functions of, 115, 189, 780-83
 - growth (equivalence) in, 726
 - level regulation, 249-50, 253
 - metabolism, 188-89
 - and gonads, 188
 - and milk fever, 189-90
 - and parathyroids, 188
 - and thyroids, 188
 - dietary source of, for rapid growth, 783, 795, 798, 802
 - and milk production, 189
 - to phosphorus ratio, 191, 249, 807
- caloric equivalents of O₂ and CO₂, 35-6, 310-2
- calorigenic effect
 - of drugs, 60-61
 - of foods (see SDA)
 - of hormones, 60-61
- calorimetry (see biocalorimetry)
- cancer
 - death from, 700
 - incidence and mechanisms, 144-45
- carbohydrate
 - level regulation, 248-49
 - metabolism
 - and the adrenals, 192
 - influence of cortin on, 184
 - hormones in, 191-94
 - and insulin, 192
 - and pituitary hormones, 192
 - oxidation of, 308, 310
 - R.Q. of, 309
 - SDA of, 61-70
- carbon dioxide
 - photosynthetic assimilation of, 130
 - production
 - age curve of, 503
 - diurnal rhythm of, 236
 - removal from blood, 113
 - utilization of, 129
- carbonic anhydrase, 113
- carboxylase, 112
- carboxylation by saprophytes and liver tissue, 129
- carcinogens, 144
- Carnot engine and equation, 15
- carotene (see vitamin A)
- carriers in biologic oxidation, 138
- casein (see milk)
 - in relation to methionine and choline, 128

- castration
 and genital cancer, 144-45
 influence on growth, 165-66
 catabolism and anabolism, 129
 catalysts
 endogenous, 109-10, 120, 140
 enzymes as, 108, 110
 exogenous, 109-10, 120, 140
 hormones as, 109-10, 140-205
 vitamins as, 109-10
 cell division, 485-86
 cephalisation coefficient, 607
 cerebral metabolism, 407-9
 Chastek paralysis, 122
 cheese, composition of, 789
 chemical-temperature regulation, 264, 282-83
 chest girth
 in relation to body weight, 596-97, 628-30, 650-57
 for estimating weight, 653-57
 chick embryo, influence of temperature on, 271-74
 chlorophyll, relation to hemoglobin, 113
 cholesterol, 142-43, 154-55
 and aging of blood vessels, 690
 in egg, 875
 hormone and vitamin derivatives of, 143
 nucleus, 142, 154-55
 choline, 117, 127-28, 133
 circulation
 and aging, 699
 and work capacity, 923-38
 citrin (vitamin P or hesperidin), 134
 cleidoic nature of egg, 490, 875
 clothing and temperature, 303-4
 cobalt, 101, 112, 115, 137
 cocarboxylase, 110, 119
 coenzymes, 110
 coenzymes I and II, 124
 coenzyme R (see biotin)
 colloidal theory of aging, 672-74
 colostrum, 810-12, 847
 combustion values of some nutrients, 36
 comfort zone, 283-84, 286
 compensation theory of SDA, 65
 conductance of heat, 274, 277, 293
 convection of heat, 274, 277
 copper, 101, 113, 115, 137
 coronary circulation
 and work capacity, 923-24
 corpus luteum, 157, 160
 corticosterone, 150
 cortin, 184-86
 and adrenaline, 184
 and carbohydrate metabolism, 184
 and metabolic rate, 185
 and nitrogen metabolism, 185-86
 and salt and water metabolism, 184-85
 under stressful conditions, 185
 and body weight, 186
 cost of nutrients, 788-90, 801, 876
 creatine, 19, 104
 creatinine nitrogen, 363
 numerical data on, 394-95
 prediction table for, 397
 relation to body weight, 378, 382
 cretinism, 168, 171, 183
 cyanide, effect on metabolism, 114
 cytochrome in metabolism, 107, 113-15
- ## D
- "dairy merit"
 definition and evaluation of, 853-55, 857-58, 864
 and profit, 864-65, 870, 872-73
 death
 causes of, 664, 676-77
 as end point of a chain of processes, 664, 700, 706
 probabilities of, 700
 decarboxylases, 108
 decarboxylation reaction, 130
 7-dehydrocholesterol (vitamin D₃), 135, 143
 dehydrogenases and dehydrogenation, 105, 108, 114, 138
 desoxycorticosterone, 150
 detoxicant, ascorbic acid as, 121, 134, 138-39
 development (see growth), 486
 diabetes, 192
 and overfeeding, 690
 diet
 and aging, 689-98
 and destiny, 741
 and hormones, 152-53
 palatability of, 757
 and temperature, 302-3
 vitamin proportions in, 766
 dietary
 deficiency diseases, 743
 factors, species differences in need for, 741-44
 selection, 744-52,
 standards for man, 769, 786
 standards for different species, 470-83, 768-71
 differentiation and development, 46, 489
 dinitrophenol, 172
 diseases
 of adrenal cortex, 184-85
 dietary deficiency, 743
 incidence and aging, 696-97
 dimensional analysis, 590-99
 diminishing increments, principle of, 76-99
 and efficiency of egg production, 3, 95
 and food consumption, 86-91
 and efficiency of milk production, 5, 91-95
 and net-energy values of feeds, 79-86
 and efficiency of muscular work, 6-9, 96
 diurnal rhythms, 232-42
 of muscular activity, 234, 236, 240
 and "alkaline tide", 235
 in blood composition, 235
 in bodily functions, 235
 in egg production, 235
 in feeding, 234
 literature on, 233
 in metabolic rates, 232-33, 236-41
 in milk composition, 235, 241
 in nervous irritability, 234
 and seasonal rhythms, 232, 241
 apparent effect of SDA on, 233, 240
 in sleep, 233
 in temperature, 233, 237
 and nature of visual apparatus, 232

- domestication, effects on seasonal sex rhythms, 207, 210-11
- drugs
 - calorigenic effect of, 60-61
 - effect on work, 926
- dwarfs, types of, 196

E

- efficiency, energetic
 - of cadmium standard cell, 37
 - capacity and intensity factors in, 16
 - and declining birth rate, 964-65
 - in relation to over-all economy and profit, 1-2, 853-74, 890-906, 944, 960-61
 - of egg production (see under egg)
 - and free- and net-energy concepts, 14-16, 54-57
 - of engines, 15, 37, 903
 - and entropy tax, 42
 - equations and definitions of, 2, 10, 15, 38, 902, 906, 910
 - factors in, 1, 17, 20, 959-65
 - of farm animals, 55
 - general and thermodynamic aspects of, 1-11, 15-33, 37-58, 960-61
 - of growth (see under growth)
 - of kidney work and SDA, 20-21, 65
 - intermediate and long-range, 1, 959
 - and maintenance cost, 4-5
 - of meat production (see under growth)
 - of milk production (see under milk)
 - of photosynthesis, 22
 - and physiologic age, 49, 53, 722, 740
 - of production of different foods, 790-91, 960
 - of muscular work (see under work)
 - effect of vitamin deficiency on food utilization, 100-101
- effort, muscular
 - ratio of maximum to rest, 915
 - ratio of sustained hard work to rest, 915-17
- egg
 - caloric value of, 877
 - cells, 485-88
 - cholesterol in, 875
 - cleavage of, 485-90
 - cleidoic nature of, 490, 875
 - compared with milk, 787-91, 801, 875-76
 - composition and nutritive value of, 875-80, 894-95
 - cost of nutrients in, 875-76
 - division of in twin production, 202-3
 - endocrine relation, 875
 - fertilization of, 485
 - follicles, 156-57
 - nature of fuel in, 875
 - metabolic relations, 875
 - morphology of, 877-79
 - physicochemic relations, 875
 - weight, 877
 - and body weight, 482, 891, 893
- egg production
 - as aging index, 675, 710
 - and diminishing increments, principle of, 3, 95

confinement method, 346

Grafe's open-circuit chamber, 347

Haldane, 331-33

open-circuit, 336-37

Regnault-Reiset, 326-28

basal, 59-67

of mature birds of different species, 371

definition of, 4, 59, 138, 352

of growing animals, 371-72

of mature animals of different species, 368-70, 388-89

maintenance cost and efficiency, 4, 470-71

and neuroendocrines, 359-60

numerical data for, 388-89

prediction table for, 397

and productivity, 470

as reference base for SDA, 68

and the surface law, 354, 360, 387

effect of temperature on, 294

relation to body weight, 352-403

of beef cattle, 463, 464, 468

metabolism, calcium-phosphorus, 188-91

carbohydrate, 184, 191-94, 954-55

cerebral, 407-9; and brain size effect on, 620-23

of chick embryo, 430-31

of chickens, 448, 450

computed from R.Q. and urinary nitrogen meth-

ods, 311

of dairy cattle, 409-18, 446-47, 452-53, 461, 462,

467

by dimensional analysis, 591

diurnal rhythms of, 232-40

fasting, 406

and fetal weight, 428, 431

gestation and pre-natal, 427-42

of goats, 419

and growth, 50, 485-89

and hormones, 145, 168

of horses, 420-25, 454, 455, 464, 466

interrelations between physiologic functions and,

355-56

of man, 424-28, 446, 458-59

methods of measuring (see biocalorimetry), 307-51

and milk yield, 856

nitrogen, 185-86

post-absorptive (see basal), 352

protein, 353, 377, 379

of rate, 405, 406-9, 461

resting, 59, 352, 406

salt, 184-85

seasonal rhythms in, 22, 226-28

of sheep, 462, 463, 468

standard (see basal), 352

standing vs lying, 423

summit, 283, 284, 289

and surface area, 405, 407

of swine, 447, 456-57, 465, 466, 469

and thyroids, 172, 624

and body weight, 404-69, 581-82, 584

during work, 912

methane

in gas analysis, 339-40

losses, 82-83

in measuring heat production, 319, 322-23

production, 24-31, 319, 323

methionine, 122, 128

milk, 792-874

antirachitic value of, 802

use in bread making, 799

use in buttermaking, 800

calcium and phosphate in, 807

caloric value of, 806

colostrum, 810-12, 847

composition, 804, 807

of average market, 794-95, 798, 801, 846-47

compared to blood, 807-8

calcium-phosphorus ratio, 807

in different cattle breeds, 805-6, 848-52

of cheese, 789

immunological in, 805

influence of dietary composition on, 807, 817-19

diurnal rhythm in, 235, 241

influence of fasting on, 819-20

individual, within breed, 806, 849-52

effect of mastitis on, 808

milk composition, calcium-phosphorus ratio, effect
 • of milking frequency on, 807-8
 in terms of milk solids, 806
 and physiologic age, 804-5
 of fluid skim milk, 789
 of skim milk powder, 789
 effect of stage of lactation on, 811-14
 in different species, 804-7, 847
 of fluid whole milk, 789, 846-47
 of whole milk powder, 789, 799
 constituents, 794-99, 802-4
 market prices of, 788, 801
 synthetic powers of mammary gland for, 807-20
 consumption
 effect on growth, 795-99
 and income, 787, 803
 as an exclusive diet, 804
 fatty acids in, 846
 fever, 189-90, 808
 importance of lactose in, 802
 nutritional and social importance of, 792-94
 and the organismic theory, 799
 O-R potential of, 108-9
 osmotic pressure of, 808
 physical properties of, 794
 production
 as aging index, 679-83, 686-95
 average in U.S., 853
 biological interrelations in, 792, 848
 and calcium, 189
 capacity (effective body size) factor in, 873
 compared in cows, goats, and rats, 851
 and grain consumption, 92-95
 and TDN consumption, 92-93
 and the law of diminishing increments, 91-95
 economy and cost of, 793, 853-74
 efficiency
 capacity and intensity factors in, 873
 compared with egg production efficiency, 53-55, 793, 960
 comparison with growth efficiency, 53-54
 and TDN and grain consumption, 92-96
 equations for, 2, 10, 78-81, 91-96, 827-42
 in goats, cows, and rats, 857
 and basal metabolism, surface area, maintenance cost, 856-57
 and milk production level (law of diminishing increments), 5, 91-96
 and physiologic age, 53-55
 tables for estimating, 861-63
 and body weight, 53-54, 471-73, 535, 836-42, 853-68
 equation for, 78
 hormonal theory of, 157-58, 160-61
 importance of, 792-93
 improvement in, 854
 intensity (dairy merit) factor in, 873
 maintenance cost and "basal metabolism", 856
 method of estimating feed consumed for, 843-45
 effect of milking frequency on, 809
 and neuroendocrine regulation, 252
 and plane of nutrition, 853, 870
 performance, 853-54
 percentage conversion of TDN in, 853-55, 873

prediction of, 854
 reference bases for, 855-59
 effect of stage of lactation on, 811-14, 833-35
 statistics on, 790-94, 846-52
 effect of temperature on, 295-96
 effect of thyroid medication, 175-76
 and visceral organs, 855
 and body weight, 831, 836-39, 853-56, 859-60, 864
 protein in, biological value of, 779
 rabbit, 158
 ratio to $W^{.73}$, 404
 relations between protein, fat, and lactose, 869
 souring, reasons for, 794
 "spread" from concentrate of, 799-800
 supplementary value of, 794, 799, 802-4
 vitamins in, 798, 846
 waste of skim milk and whey from, 797, 800
 minerals
 in the body, 780
 in biologic oxidations, 101, 105, 111-16, 781
 mixtures for synthetic diets, 784

 - and clothing, 303-4
 - coefficients, 267-71
 - critical, 279, 283, 294

- temperature, and diet, 302-3
 - diurnal rhythms in body, 216, 223, 234, 237, 297
 - and productive efficiency, 294-98, 304
 - and exercise, 304
 - and feed consumption in dairy cattle, 296
 - and fever, 200-1
 - and growth of chickens, 297
 - and hatchability, 274
 - and homeothermy, 305
 - and humidity, 302-3
 - incubation, 271-73
 - and longevity, 684-85
 - and methods of cooling in hot weather, 298-99
 - and milk production, 295-96
 - and pulse rate, 281-82
 - and productivity, 294-98
 - rectal, 265, 280-2, 293-95
 - and reproduction, 298
 - and respiration rate, 280-81
 - and speed of biologic processes, 269-70
 - and body surface, 290
 - and heat production in dairy cattle, 296
 - and heat production in birds, 283, 287-88, 290
 - and heat loss, 277-80, 291
 - relation to SDA, 65
 - and rate in poikilothermic processes, 266, 270
 - thermodynamics, 12-36
 - and agriculture, 20-23
 - applicability to living processes, 12-15, 18-20
 - aspects of muscular work, 900
 - and industrial progress, 966
 - first law, 12-14
 - second law, 14-23
 - symbols, 33
 - thermogenesis (see heat production)
 - thermogenic reserve, 284-85
 - thermolysis (see heat loss)
 - thermoneutrality, 283-84, 286
 - thermoperiodism, 209
 - thiamine (vitamin B₁)
 - and alcoholism, 122
 - in biologic oxidation, 100
 - and Chastek paralysis, 122, 774
 - deficiency effects, 100, 119
 - formula of, 117, 123, 132
 - function of, 100, 119, 132
 - needs, 120, 474, 769, 786
 - as prosthetic group of coкарбоксylase, 110, 119
 - sources and costs of, 769, 787-91
 - and sulfa drugs, 122
 - as supplement to riboflavin, 121, 122
 - and Wernicke's disease, 122, 175
 - thyroid
 - administration of, 172-76, 183-84
 - effect on egg production, 175
 - effect on growth and development, 168-78
 - effect on milk and butterfat production, 175-76
 - and adrenal medulla, 179-81
 - applications, 183-84
 - and calcium metabolism, 178, 188
 - deficiency effects, 168
 - and gonads, 182
 - and iodine, 178-79
 - and metabolic rate, 172, 289
 - and the nervous system, 182-83
 - and nutrition, 177-79
 - and the pituitary, 181-82
 - and rejuvenation, 175
 - seasonal rhythms in composition and activity, 213-14
 - and sterility, 174-75
 - and body weight, 621-22
 - thyroidectomy, effects, 168, 172
 - thyroxine
 - calorigenic effect of, 179-80
 - and goitrogenic drugs, 144
 - in hyperthyroidism, 179
 - in hypothyroidism, 179
 - production of, 110
 - tidal air, 919
 - time
 - physical, 712
 - physiological, 712-13, 739
 - as frame of reference, 712
 - total digestible nutrients (TDN) 6, 30, 32, 34, 475-80
 - consumption and milk production, 92-93, 643-45, 848-52
 - percentage conversion into milk, 853-55, 873
 - in relation to gross and net energy, 34, 80-89
 - trace elements in catalytic oxidation, 116
 - transaminases, 108
 - trophic hormones, 146
 - trophoblasts, 491-92
- ## U
- uncertainty, principle of, 259
 - units, bioenergetics and dietary, 23-38, 765-66, 768-71, 779, 784, 786-91
 - urea, uric acid, 353
 - urinary-nitrogen
 - in computing energy metabolism, 309-11
 - endogenous and exogenous, 353
 - and SDA, 67
 - urine
 - energy losses in, 82-84
 - hormones in, 152, 159
 - method of collecting in rats and cattle, 382, 384-86
- ## V
- vanadium, 116, 137
 - van't Hoff-Arrhenius equation, 718
 - vaporization
 - heat of, 307
 - heat loss by, 277-81, 291-92
 - and environmental temperature, 277-80
 - ventilation, pulmonary, 409-23, 452-56, 919-20, 929, 951-53
 - in dairy cattle, 415, 452, 453
 - in horses, 423, 454-55, 919-20, 929, 951-53
 - maximal, as fitness index, 929
 - and metabolism, 415, 418
 - and oxygen decrement in expired air, 416
 - rate, measurement of, 335
 - reserve, 930
 - during standing, 910
 - in swine, 456
 - and temperature regulation, 280-82, 415-16, 929-30
